TREATMENT OF ULCERATIVE COLITIS

William J. Grace, M.D.
and
Harold G. Wolff, M.D., New York

The long-term management of patients with chronic ulcerative colitis is difficult, and the usual therapeutic regimens are often unrewarding. For many years various etiological agents have been postulated, including bacteria,[1] viruses,[2] enzymes such as lysozyme,[3] food allergies,[4] and vitamin deficiencies.[5] Eventually the evidence on all of these has been inadequate.[6] The present-day chemotherapeutic agents and antibiotics are apparently useful only in some acute febrile exacerbations of the disease.[7] Their failure to basically alter the course of the disorder indicates that microorganisms are probably not involved primarily. Murray [8] noted that the onset and each exacerbation of the disease occurred during periods of stressful life situations. Many investigators have corroborated and elaborated his findings.[9] Experimental studies have demonstrated the relationship between life stress and ulceration of the colonic mucosa in man.[10]

This report is based on the study of 19 unselected persons with chronic ulcerative colitis. The entire management was in the hands of one physician, who had as adjunct the services of a social worker.

OUTLINE OF THE MANAGEMENT OF THE PROBLEM

Treatment was carried out in interviews spaced at intervals of a few days or weeks, according to the apparent needs of the subject. In the interview the physician's role was that of a detached but interested, reliable, consistent and, supporting confidant. The interviews, by encouraging the patient to express himself freely, to engage in introspection, to recall, relate, and interpret dreams, and to make associations with his thoughts, feelings, and life events, were directed toward bringing about in the patient an understanding of himself and encouraging him to a more constructive orientation toward his life and the people in it.

The greatest benefit to the patient was a constructive physician-patient relationship. The patient was given opportunity and was encouraged to express with a free show of feelings, to a sympathetic and appreciative physician, the major complaints and difficulties in his life situation. The physician never criticized such feelings. He encouraged the patient to express his thoughts, and to be confident that such attitudes would not threaten his relationship with others or exclude him from the love of his closest relatives. Ambivalent feelings toward a spouse or parent were discussed, and the universality of such attitudes was explained.

Encouragement and support of the patient were freely given by the physician. These employed the warmth of human relationships. The patient's own assets and accomplishments were emphasized in building the self-esteem and self-confidence of the patient. A tolerant attitude on the part of the physician was essential. No problem could be too small to consider, and interviews

with spouses and relatives were often necessary. Special consideration was given the patient during periods of unusual stress. The patient was made to feel free to telephone the physician at almost any time. Patients were permitted to make appointments at an earlier date than the one agreed on when unexpectedly difficult situations arose. During times of severe symptoms, the patient was seen frequently, as often as daily should the needs of the patient require such care.

Patients were given an explanation of the disease process, and this was repeated at suitable intervals, such as during periods of severe symptoms. Emphasis was placed on the participation of the bodily viscera in different moods and feeling states. In addition to the usual "routine" medical history, a detailed personal biography was undertaken. Periods of illness were correlated with periods of emotional stress.

The background, the family, the cultural setting, the emotional responses, and the aims and ambitions of the patient were explored in order to understand the patient and to help him to understand himself. In some instances it was possible for the patients to recognize the basis of their feelings and attitudes (for example, in the light of their childhood experiences) and to alter them significantly and for the better (case 1). However, many patients were unable to incorporate this knowledge into their daily behavior, and symptoms did not change. In such instances it was felt better to have the patient realize and accept his dependent position and to make the best of it, rather than to try to alter it. That the need to be cared for and loved is universal and acceptable was emphasized, as was the fact that attempts to reject the dependency are often more disastrous than the acceptance of a dependency.

The patients were instructed in means of recognizing their own manifestations of accumulating emotional tension and encouraged (1) to accept them for what they represented and (2) to attempt to deal with the circumstances leading to their presence. When the patients learned to appreciate the origin of their symptoms, they often no longer looked on them as the manifestations of a dire disease. This later phenomenon in itself helped to alleviate anxiety.

Finally, rearrangement in the environment was attempted. When successful, it produced dramatic results in terms of symptomatic relief (case 3). Unfortunately, however, this was not always feasible, often because of the lack of a practical maneuver, lack of cooperation of the family, or because of the inability of the patient to accept any drastic change.

No medication was given to the patient. The management was worked out with the patient. The patient's ability to utilize his own resources determined the final result. The physician guided him, helped him understand why he was getting into difficulty, and supported him when he was trying to alter his environment or attitudes.

Time factors were of the greatest importance in this type of management. In many instances, in hospital circumstances, an apparently spontaneous recovery took place in two or three months, representing the therapeutic effect of the passage of time and of autonomous biological forces.

The passage of time in itself was often helpful in establishing the patient's confidence in his physician. The increase in confidence frequently alleviated inhibitions and reluctance to express feelings and attitudes. Moreover, an appreciation of the appropriate moment for introducing a new concept or challenging an established attitude was essential.

Thus it would have been unwise when the patient was disturbed or having severe symptoms to threaten his security system in anyway. Difficulties in the life situation were often anticipated so that interviews might be arranged to antedate an approaching unpleasant event, such as school examinations, the undertaking of a new position, or the approaching visit of an unwanted relative.

RESULTS

During this type of management 11 of the patients showed substantial improvement. Of these 11, four patients became free of symptoms and remained so for more than a year, one of these for three years. Two patients showed slight improvement over a year and a half. Six of the 19 patients did not improve. Of these six, one died and one has had an ileostomy. These results are compared with other published series in the table.

Evaluation of the Clinical Management of Chronic Ulcerative Colitis

	Results of Treatment in Terms of Control of Symptoms			
	Cases *			
Author	Number	With Good Control, %	With Fair Control, %	With Poor Control, %
Kiefer	327	34	12	54

Present series	19	56 (11 cases)	12 (2 cases)	32 (6 cases) (1 dead)

* Cases followed two years or more.

In the group there was no direct relationship between the patients' age, duration of illness, severity of illness, and extent of x-ray changes, and the patients' ability to recover from the illness, or to make a significant improvement.

In considering the features responsible for improvement or failure to improve in the patients studied, a number of facts became apparent which are illustrated in the following case reports.

Chronic ulcerative colitis occurred in a setting of intense unexpressed hostility. A basic alteration in attitudes by the patient was followed by diminution in hostility and disappearance of symptoms in three of the 19 patients. The following protocol describes the moderately severe ulcerative colitis which began in a 36-year-old woman in a setting of intense hostility toward her husband. During a series of 17 therapeutic interviews over a six-month period the patient was able to modify her attitudes and feelings toward her husband. This change corresponded with marked symptomatic improvement, and x-ray and sigmoidoscopic studies at the end of six months revealed no evidence of ulcerative colitis. She has been free of symptoms for three years (Fig. 1).

CASE 1.—A 36-year-old graduate nurse had ulcerative colitis with continuous symptoms for four years. When symptoms were very severe she had 12 to 24 bloody rectal discharges a day.

She married, at the age of 30, a man 15 years her senior, after having rejected many suitors. Her fantasy that her husband would be a "perfect" man was soon dispelled. He was responsible for the financial welfare of his two elderly parents. This took considerable time and money as the old people were demanding of his presence and affection as well as a financial drain. He spent much time with them. As time went on the patient began to feel that he cared less for her than for his parents, and that he had many ideas and notions quite different from hers. She "felt like leaving him many times," although she did not, being afraid that she would be unable to support herself. In this situation of conflict she became more and more resentful toward him and became enraged at his slightest defect in behavior. However, she was unable to express any of this hostility, being concerned lest he leave her. She remained smiling, and no friend or acquaintance knew of the marital strife. As she became more and more uncertain of the wisdom of continuing the marriage, and bitter and resentful toward her husband, ulcerative colitis began insidiously four years before she came to the New York Hospital. She had been attended by several physicians and had had numerous diagnostic investigations.

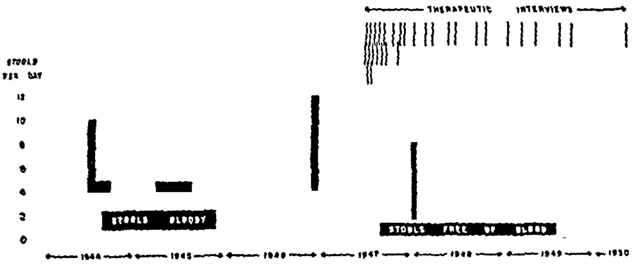

Fig. 1 (case 1).—Alteration in the course of chronic ulcerative colitis following institution of therapeutic interviews. Each short line represents one interview. The rapid decrease of the diarrhea and disappearance of blood from the stools can be noted. The patient continues to be free of symptoms even though she is being seen very infrequently. A marked change in behavior and attitudes was found to be associated with a rapid diminution in symptoms.

At the time she presented herself to the hospital, sigmoidoscopic examination revealed an engorged, hyperemic, friable, ulcerated mucus membrane as far as 22 cm. up the bowel. X-ray examination revealed spasm and shortening of the descending and sigmoid colon. Repeated cultures of the stools for pathogenic organisms and amoebae were negative.

The patient was interviewed for a total of 26 hr. She was able to work out the dynamics of her behaviour and motivations and gradually became able to accept her husband and his faults and to make the best of the situation. She found her husband sympathetic toward her in regard to her attitude toward his parents, and that he was able to tolerate outbursts of anger on her part and give her understanding. After six months the sigmoidoscopic and x-ray examination showed no structural change and the subject was not passing blood or mucus through the rectum. It is probable that this woman will be able to deal with her personal affairs more adequately in the future and remain free of ulcerative colitis. After the first six months of therapy she was seen only once in three months. She has remained symptom-free for three years.

The opportunity to express feelings of anger and hostility to a sympathetic physician was found to be sufficient to diminish the intensity of such feelings. The tranquility brought about by a good physician-patient relationship was often found sufficient in itself to result in the disappearance of symptoms even in the absence of any basic alteration in attitudes. Diminution in symptoms occurred in 5 of the 19 patients associated with these phenomena. A 35-year-old woman, discussed in the following protocol, had had severe ulcerative colitis for four years. After the establishment of a good relationship with her physician, there was a prompt diminution in symptoms, and ultimately x-ray and sigmoidoscopic examination revealed no evidence of structural changes (Fig. 2).

Case 2.—A 35-year-old woman had had severe ulcerative colitis for four years prior to coming to the New York Hospital in May of 1947. Her early life in Puerto Rico was one of extreme poverty and parental rejection and domination. At 18 years she came to the United States to seek a more comfortable life. At 21 she married a passive, dependent, indecisive man, who thrust the entire burden of family responsibility on her shoulders. She worked hard keeping her home neat and clean, and supplemented her husband's inadequate salary by doing factory work. She experienced gradually increasing resentment toward her husband during the years of their married life, and began to feel that she was living the life of a "drudge," which she had tried to escape. In a setting of intense resentment toward her husband, and a feeling of desperation over having lost a job through no fault of her own, acute ulcerative colitis began. The bloody diarrhea continued with frequent acute exacerbations up to the time of hospitalization, during which time she would have 12 or more bloody rectal discharges daily. Examination at this time revealed a severely ulcerated, friable mucus membrane from the rectum to the sigmoid colon. Barium enema showed extensive changes consisting of ulceration and narrowing and shortening of the entire colon. Repeated stool cultures failed to reveal any amoebae or pathogenic bacilli. The Frei test was negative. In the hospital she had a protracted febrile course, receiving penicillin and sulphaguanidine without benefit. An ileostomy was considered advisable, but deferred until an attempt to deal with her personal problems had been made.

During the first two hours of interview, she was extremely reticent and unable to deal with questions concerning her personal life. When it was suggested that she simply recount her biography in her own way, however, she was able to talk more freely. Shortly thereafter she began to feel better. Her appetite improved and bowel movements were less frequent (Fig. 3). She was discharged from the hospital without operation early in August, 1947, and continued to visit the Outpatient Department. Despite her improvement there was little reason to think that it would be sufficiently sustained to lead to recovery. Moreover, her rigid attitudes and difficulty with introspection and communication made it seem unlikely that she would benefit from any therapy short of surgery. Nevertheless, by the latter part of November, 1947, sigmoidoscopic examination showed a normal colon and her symptoms had almost entirely disappeared. At that time she was having one or two loose bowel movements a day, but she passed no blood.

She said that since she had been treated with attention to her life problems and conflicts she felt generally better and more tolerant of her husband's lack of cooperation.

Over the period of the next 12 mo., during which she was visiting the clinic at frequent intervals, her symptomatic improvement was maintained. At the end of this period there were no symptoms of ulcerative colitis and she was having one or two normal bowel movements a day, without blood or mucus. The patient said that she was feeling calm and at peace, relatively relaxed, and better than she had ever felt before the onset of her illness. Her attitude toward her husband and her children was more tolerant. She continued to do her housework as carefully as ever, but did not drive herself as before. Temper outbursts continued, but she brooded much less. Now her general

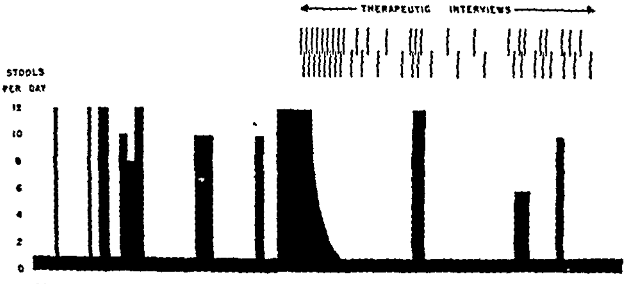

Fig. 2 (case 2).—After the establishment of a good physician-patient relationship through therapeutic interviews, the episodes of acute bloody diarrhea became less frequent and shorter in duration. There was no significant change in environment or attitudes of relatives. Each short line represents one interview.

aspect was more buoyant and cheerful, and her statements of *improvement were more convincing. She was slowly learning to deal with herself, and the prognosis now seemed good.*

During the first year she was free of symptoms, but during the second year of "follow-up" she had transient periods of bloody diarrhea in settings of mounting suppressed anger directed toward her children (Fig. 3).

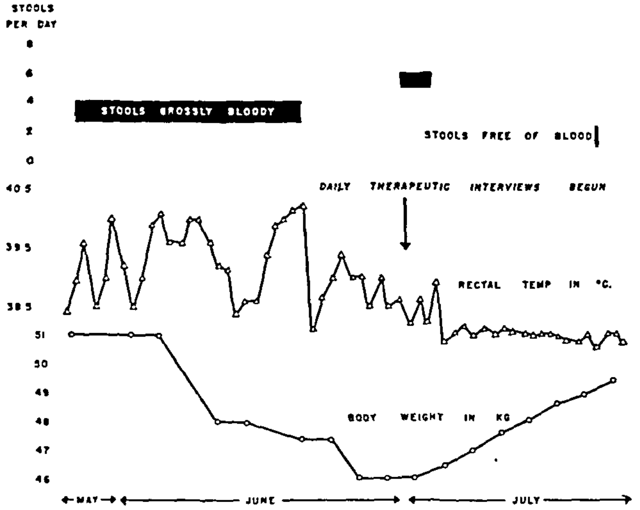

Fig. 3.—This diagram shows the hospital course of the patient described in case 2. After the institution of daily therapeutic interviews, there is a rapid diminution in the diarrhea and a disappearance of blood from the stools. At the same time a defervescence and a rapid gain in weight began.

A radical change in environment for the patient minimized the number of occasions which precipitated intense feelings of hostility. The subsequent calm and security resulting from the altered environment was found to bring about a striking reduction in symptoms without basic personality change. The following protocol describes this phenomenon in a 29-year-old woman in whom ulcerative colitis developed in an intolerable life situation. Major changes in the behavior of her husband and frequent removal of the patient from her environment resulted in feelings of calm and security and a rapid abatement of symptoms (Fig. 4). In three of the 19 patients radical changes in environment were associated with prompt diminution in symptoms.

Case 3.—A 29-year-old white Spanish Jewish woman had ulcerative colitis of three years' duration. She was the youngest child of three. A remarkably overprotected child and adolescent, she was extremely *dependent on her mother for affection and support.* She was married at 19 to a man of her family's choice and immediately transferred her feelings of dependency to him. Her childlike fantasy of a strong, decisive, independent, affectionate and demonstrative male was not fulfilled in her husband. He was a dependent, unaggressive, shy, retiring, undemonstrative man who was devoted to his mother. The mother-in-law, in whose house they lived, disliked and openly criticized the patient in the presence of her husband. The husband made no effort to defend his wife, and the patient, although she became more and more resentful about the situation, said nothing. She remained smiling and cheerful in front of her husband and her family. As time went on she became fond of a brother-in-law who was kind to her, "took my part" and "told the mother-in-law off." She stated that "he was the only friend I ever had." This man died six years after the patient's marriage. Within two days of his death, the patient, in a setting of anxiety, fearfulness, increasing resentment toward her husband and mother-in-law, and in conflict as to whether to go home to her parents or remain in her unpleasant marriage, acquired acute ulcerative colitis. She said, "I felt alone in the world. I had no one to lean on." During the three years of her illness the symptoms were never absent, *although for about four months of each year they were very mild.* Approximately twice each year she had an acute exacerbation of symptoms lasting three to six months. Each episode was invariably precipitated by an argument with her mother-in-law, in which her husband "let her down." Each episode was characterized by conflict (whether to leave the husband or not), fear of losing her husband, anger and resentment toward the husband and his mother, and an inability to express her feelings. Each exacerbation of symptoms ceased when the patient would take a "vacation by myself" or the mother-in-law would spend the winter in Florida. When interviewed for the first time, she weighed 70 lb. (31.8 kg.) and was having a bowel movement almost hourly. Her temperature was 102 F. Sigmoidoscopic examination revealed an engorged, bleeding, ulcerated, friable spastic rectum and lower sigmoid. X-ray examination revealed spasm and shortening and ulceration in the entire large intestine. She was immediately hospitalized, ordered to remain in bed, and given a diet of her own choice. She poured out all of her wrath and indignation to her physician. The latter listened sympathetically and agreed with the patient's interpretation of her problems and supported her in complaints and bitter feelings. She was encouraged to be confident that she would recover and that steps would *be taken to help solve her problems.* On the fourth hospital day she was informed that her mother would come to live with her when she left the hospital and that her father was making plans to provide a vacation for her. She was also told that her husband was being attended by the physician. Within 24 hr. her bowel movements decreased from 10 to three per day and the fever ceased (Fig. 5). She said she felt that the hospital and the physician "were my friends." Except for a mild exacerbation following a visit from her mother-in-law, the improvement persisted. She was discharged in three weeks.

During the year following, the husband had "spoken to" his *mother in the patient's presence,* and the mother-in-law did not "bother" her as much. Her mother remained with her for six weeks. In the following year the patient was seen for 25 one-hour visits, during which time an attempt was made to help her see and understand her behavior and become a more independent, self-sufficient person. At the end of a year and a half she was entirely symptomless for eight months and weighed 104 lb. (47 kg.). Sigmoidoscopic examination revealed no abnormality, and the x-ray findings indicated less spasm and ulceration of *the colon.*

The ability of a patient to participate in a constructive physician-patient relationship was found to be related to the dwindling of symptoms and, inversely, failure to do so was associated with persistence of colitis. The following protocol describes a 36-year-old woman who had ulcerative colitis for three years. She was able to discuss only certain less troublesome facets of her personal problems. She changed her behavior but little. The symptoms diminished slightly, but she had episodes of bloody diarrhea of about the same frequency and severity as

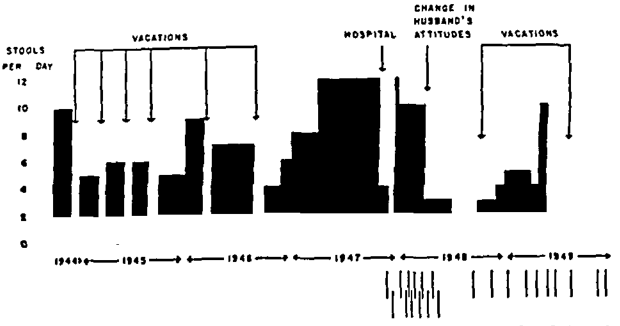

Fig. 4 (case 3).—Periods of removal of the patient from her environment corresponded with periods of freedom of symptoms. A radical change in environment or in the attitudes of relatives is often adequate to remove *the occasions of anger and hostility and to diminish* 'symptoms.

before the interviews were begun. Six patients of the 19 were unable to participate fully in the therapeutic relationship. Of these, four showed no change in symptoms and two improved only slightly.

Case 4.—A woman, aged 35, had mild symptoms of ulcerative colitis continuously for three years, having four to six bloody rectal discharges a day. She was an exceptionally rigid, compulsive person. Indecisiveness, dependency, and inability to ventilate or act out aggressive feelings, and a vicious temper were the outstanding personality features. She said "If I didn't have such a bad temper, I wouldn't have this disease." Ulcerative colitis began in a setting of increasing anxiety over caring for a newborn infant, conflict and resentment toward her mother-in-law who had moved into her home, and increasing anxiety and resentment over being unable to procure a sufficient variety of foods during the war even though she shopped for at least four hours every day. Sigmoidoscopic and x-ray examinations revealed moderate structural changes indicative of ulcerative colitis in the rectum and sigmoid area. Repeated examinations of the stools were negative for pathogenic organisms.

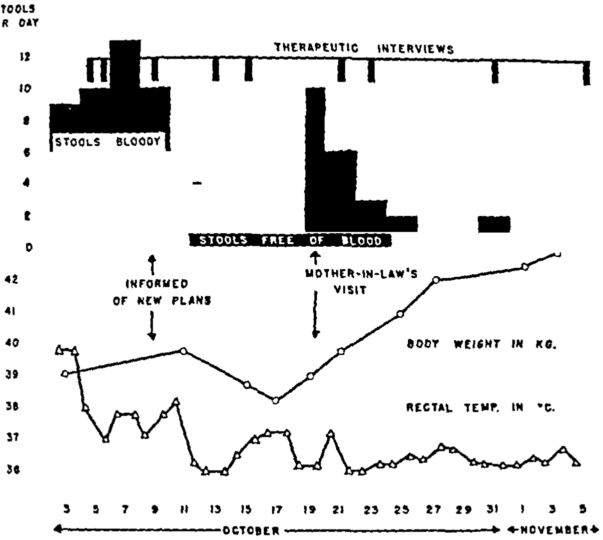

Fig. 5 (case 3).—Rapid decrease in diarrhea, fall in temperature, and weight gain following the presentation to the patient of a plan for a solution of her problems. There was a mild exacerbation during and following humiliation associated with a visit from her mother-in-law.

She has been interviewed for a total of 22 hr. over a year and a half. Although there was some improvement, she continues to have episodes of acute bloody diarrhea. Each of these exacerbations has been precipitated by situations which place her as the center of responsibility in dealing with a sick child or an irate mother-in-law. At such times she gets little or no help from her husband, who withdraws from the scene.

The patient has not taken full advantage of all of the potentialities of the therapeutic relationship and has made only feeble attempts to understand and to help herself. There are still many facets of her life which she refuses to discuss. The slight improvement which has been seen is probably attributable to the improvement in the environment; that is, the child has grown older and is less difficult to deal with, and, the war being over, shopping is easier.

When the patient was unable to give up an unworkable behavior pattern and an excessively costly set of values the clinical course was protracted. This phenomenon was seen in two patients. The protocol of one of these is given below (Fig. 6).

Case 5.—A 20-year-old white man had been ill with ulcerative colitis for one year and usually had eight to 10 bloody bowel movements per day. He was a tall youth, had a large skeletal frame, and was heavily muscled. Except for clubbing of the fingers and toes and a small perirectal abscess, the physical examination was unremarkable. X-ray pictures taken after barium enema showed narrowing and spasticity of the descending and sigmoid colon. In addition, there was extensive destruction of the mucus membrane and ulceration in this same area. There was a constant narrowing of the sigmoid colon. Sigmoidoscopic examination revealed marked hyperemia, engorgement and fragility. There were numerous petechial lesions and tiny shallow ulcerations throughout the rectum. Intense spasm at the rectosigmoid region prevented further passage of the instrument. Repeated examinations of the stools failed to reveal pathogenic organisms.

The patient was the first of two children of American-born Catholic parents of Irish stock. His mother was overprotective and oversolicitous but had little ability to demonstrate feelings of warmth and affection toward her children. She was the dominant figure in the household, made the important decisions, and handled the money. She repeatedly indicated that her husband was a poor provider and hinted that she expected help from her sons as they grew older. After the patient's illness began, she prepared his meals, rigidly adhering to a prescribed diet, spending extra money for special foods and berating him when he did not eat them.

The patient's father, a laborer, was described as "easy-going," "nothing bothers him," "doesn't care about anything." He had no particular hobbies or interests and was content to "sit around the house and do nothing."

The patient's brother was "easy-going" like the father. The patient looked on both the father and brother with scorn.

Because of "feeding difficulties" and vomiting in infancy and because the mother was working to supplement the family income, the patient spent most of his first year of life in a Catholic orphanage. After this he lived at home. Except for the common diseases of childhood, he was healthy until his first and second years of grammar school, when he suffered from many attacks of vomiting and lost so much time from school he had to repeat a year. These years corresponded to his brother's first and second years of life. The patient did poorly all through grammar school and played "hookey" frequently. He was an angry child, known to be "bad-tempered" and engaged in many street fights. Although he never "picked a fight," he had a "chip on his shoulder" and never avoided a fight. He was known as a "rowdy" and troublemaker in the neighborhood, and most of the children were afraid of him because he frequently struck them. He got along poorly with his younger brother, considered him a "nuisance" and a "pest," and would often strike him. He was "very close" to his mother and saved most of his spending money to buy her presents.

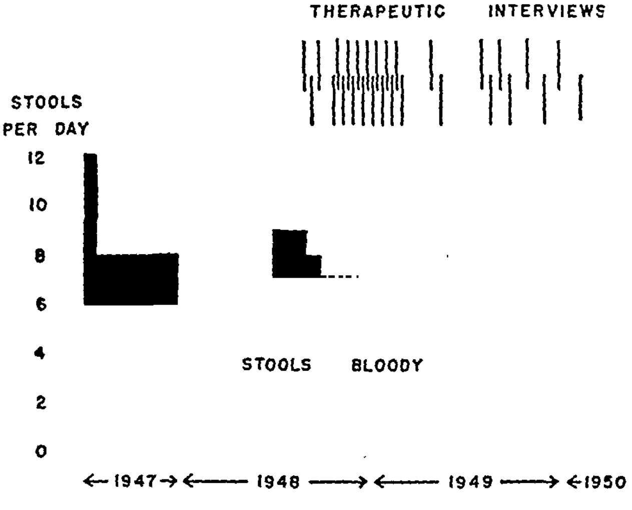

Fig. 6 (case 5).—Severe symptoms continue in this 20-year-old man, who was unable to utilize his understanding of himself in altering his behavior. The inability to alter one's behavior or to give up an unworkable set of values is associated with a protracted course.

The brother, when going to school, was a "good boy," obedient and quiet, receiving good grades. The family prodded the patient with these facts and "teased" him, indicating that his brother might "pass" him in school. He was frequently told that he should be "more like his brother." The patient said he wanted people to like him, but he was always getting into fights and into various kinds of trouble for breaking windows and for street-fighting. Once, a boy who had been "beaten up" by the patient struck his head on a curbstone and "almost died." Toward the end of his grammar school experience and the first year of high school, a change took place in the patient. He stopped fistfighting and began to try to win approval from his parents and his friends by "being nice." He attributed this change to being afraid of hurting someone while fighting, or latterly, of getting hurt himself. He began to study hard in school to "beat his brother" and to "make up" the year of lost school work. He took a job after school hours to "make money" to buy things for the house and for his mother.

In his third year of high school he pushed himself exceptionally hard in order "to make the four year course in three and one-half years." He resented his school work, felt that it was "wasted time," "gets me nowhere" and only put off the time when he could get a "steady job." He "hated it," yet he forced himself to do the school work. At the same time his part-time job continued. He saved enough money to buy an electric refrigerator for his mother. She accepted this gift "as a matter of course," thanked him for it, but did not extend the amount of gratitude and affection he anticipated. His father barely noticed it. He became bitterly resentful toward them, but said nothing. A short time later he was to take his final school examinations. In this setting of increasing anxiety, anger, and resentment toward his family over the humiliating gift episode, and his failure to win overt manifestations of their approval, he began to notice loose, watery diarrhea, which in a few weeks became bloody. In spite of this illness he finished his high-school work, graduated as he had planned at the end of three and one-half years, and went to work as an assistant printer. During the ensuing year his symptoms continued, the patient having eight to 10 loose watery bowel movements, usually containing blood and mucus. After a slight exacerbation of his complaints and the development of a perirectal abscess, he was admitted to the hospital for study.

He was usually smiling and pleasant. He said that he never showed his feelings, saying "People don't like you if you're mean." Although he was aware of a strong quick temper, he never allowed it to show itself, covering it up with smiling. He likewise had difficulty in showing feelings of love and warmth. "Little things," such as losing a bowling match, or being "out smarted" by his companions in an exchange of "wisecracks," would precipitate rage in him. He saved his money meticulously so he could buy his mother more gifts, and, indeed, purchased a new rug and kitchen flooring the following year. He wanted to be "top man" in anything he did. He felt that he had to be the best in bowling, baseball, earning capacity, money saved, and "fancy" clothes. If one of his friends said he had slept for twelve hours, the patient would "top" him by saying he had slept for thirteen hours. When defeated in bowling, he would be angry and "sulk" for hours. In spite of this competitive feeling he was not a leader in his group. He did "anything the rest were going to do." He avoided any circumstances which might put him in an embarrassing or humiliating situation. Although he wanted to learn to drive an automobile, he never accepted his friend's offer to teach him as he felt the friend would "laugh at him" while he was learning. The patient was fastidious about his personal belongings. "Anything out of place drove me mad." He had a strong drive to have possession of "things." He wanted "clothes," a television set, a car, and a bank account. "Everything I saw I wanted." He wanted to work seven days per week, so he could earn more money. Weekends he felt were a waste of time. Although he was friendly and affable at his work, he was "grouchy" and "unstable" at home. His mother said he was always "crabbing" about something. If the food displeased him, he refused to eat it. He always seemed to "get up on the wrong side of the bed." Fear of displeasing others or of being "criticized" haunted him continuously.

He denied masturbation and had very few "dates," and these only when the whole "gang" went out. Girls were a "waste of time" and only made you "spend your money." Money and a bank account represented the only kind of security he knew. He wished never to "be like my old man, without a dime." He desired to earn enough money before he was 30 so that he could "retire." For a time he entertained the idea of taking a civil service job which didn't pay much but had a good pension.

This young man was interviewed for a total of 26 hr. over one year's time, during which period he worked daily. No medication was given except small amounts of ferrous sulfate, vitamin supplement and 30 mg. of phenobarbital sodium daily. The interviews revealed that he was aware that anger and anxiety were associated with exacerbations of his symptoms. He knew he was more prone to anger and was much more "sensitive" than his fellows. His competitive attitudes toward associates were linked by him to his attitudes toward his brother and father. He was unable to utilize this information in altering his daily behavior. As he said, he did "the same things over and over again." He experienced the same humiliations and frustrations in dealing with his acquaintances, and in his work. The diarrhea, consisting of 8 to 10 bowel movements a day, continued as did the passage of blood. The x-ray and sigmoidoscopic pictures did not change.

COMMENT

Comparison of this unselected group of patients with other series of patients with ulcerative colitis shows essentially the same sex and age group distribution.[11] Thorough diagnostic procedures on all the patients were carried out by us, and at other hospitals, to verify the diagnosis of chronic, nonspecific ulcerative colitis. The course of the disease prior to the institution of our therapy was entirely compatible with such a diagnosis. In each patient the onset of the disease and each of its exacerbations coincided with periods of stressful life circumstances.

The patients were extremely dependent on the approval of others. They were uneasy and anxious in the presence of angry individuals and demanded an unending show of love and affection from their parents and spouses. They needed to be "nice to everyone," and to be on good terms with everyone; otherwise they became anxious and tense. They "did things they didn't want to do" in order to placate and to keep the peace. These peace-making attitudes made it appear that these were persons of even-temper and serenity, a misconception sometimes reinforced by a "beatific" or "angelic" look.

The overdependence, the inability to tolerate hostility in others, or to express or to act out their own hostility, the inability to make decisions, the passivity, the ever-present fear of losing the good opinion of others, made for ever-increasing conflict. In the face of such a combination of oversensitivity, passivity, indecisiveness, dependency, and hostility it was extremely difficult for any one of them ever to satisfy his dreams, desires and ambitions. Hence, they were frequently frustrated and humiliated, which made them react with anger and resentfulness. The conflict arising from desire to act out or verbalize their hostility and fear of the consequences of such action precipitated in them anxiety and an exacerbation of symptoms. In brief, the patients were hostile but "sweet," anxious but "calm," timid yet rebellious. They had aggressive fantasies, but their behavior was passive.

They experienced strong feelings of guilt over their hostility, and often felt unworthy of others' love because of their anger and resentment. The guilt was felt most often in relation to either their parents or spouses. This guilt, making them feel unworthy, also made them fear the loss of the love of the person involved and made for more anxiety.

A series of features have been indicated which determine the prognosis, and have little or nothing to do with the age of the patient, the duration of the disease, or its extent. For example, case 1 was older, and had been ill for a greater length of time than case 5, yet the younger patient followed a protracted clinical course without improvement.

---

[11] Bargen.[1a] Bockus.[6]

Prugh [12] has shown that recovery has occurred in children with ulcerative colitis when they were able to display overtly aggressive behavior. In our own patients, when it was possible, such expressiveness appeared to have a salutary effect. In any case, it seems clear that satisfactory treatment of this disorder requires detailed attention to the patient's total life adjustment.

Measures, such as careful and meticulous attention to complaints, frequent examinations, diet regulation, institution of new medications, and a solicitous attitude on the part of the physician, are frequently effective in alleviating symptoms. Such measures are probably effective only inasmuch as they establish a good physician-patient relationship.

Comparison of the results of treatment in this series of patients with previously reported series,[13] indicates that the method used here is as effective as other methods. This suggests that the therapeutic factors operating in other reported series are similar to those described in this study.

SUMMARY AND CONCLUSIONS

A series of 19 unselected patients with chronic ulcerative colitis has been presented and compared with similar series in the literature in regard to therapeutic results. Eleven patients were considerably improved, two slightly improved, and six were unimproved.

Ulcerative colitis was viewed as a stress disorder. A variety of therapeutic measures designed to alleviate this stress were used and found to be effective in approximately the same proportion of patients reported by others, using ostensibly different methods. This suggests that the therapeutic factors operating in other reported series are similar to those described in this study.

A constructive physician-patient relationship was of the greatest benefit to the patient, and favorable results in treatment were not obtained without it.

JAUNDICE IN ACUTE SUBLEUKEMIC LYMPHOCYTIC LEUKEMIA DUE TO OBSTRUCTION OF THE COMMON DUCT BY PORTAL NODES

Joseph S. Bower, M.D.
and
Rafael Coca-Mir, M.D., Martinsburg, W. Va.

The object of this report is to call attention to a case of severe jaundice that resulted from an unusual obstruction of the common bile duct by enlarged portal lymph nodes. Jaundice due to obstruction of the common bile duct by portal lymph nodes has been frequently mentioned but seldom seen.

REPORT OF A CASE

A white truck driver, 29, was admitted on April 12, 1950, complaining of a swelling in the right side of the neck for 10 days. He was in excellent health until three months prior to admission, at which time there was gradual onset of pain in the chest and back. This was described as a constant, dull, aching pain across the anterior part of the right side of the chest and a constant, dull, aching pain in the right lumbar region. The pain was not aggravated by respiration or motion. He had general malaise, lassitude, and anorexia and had lost 15 pounds. In spite of this symptomatology, he continued working. Two months prior to admission a cough developed which occurred in severe paroxysms. He raised about one-half cup of mucoid sputum daily. Ten days prior to admission a throbbing developed in the right side of the neck. This persisted; then five days prior to admission, he felt a rather severe pain radiating down the posterior aspect of the right arm.

On admission, physical examination revealed a well-developed, well-nourished, robust, white man who did not appear to be acutely or chronically ill. The right anterior cervical nodes were enlarged and palpable, these being hard and matted together. The complete mass of nodes was 8 cm. in diameter and protruded 2 cm. externally. The skin over this area was tight, and there was slight tenderness on deep pressure over this area. The pharynx was moderately injected. By percussion, it was thought that the diaphragm was immobile on the right side, and this was confirmed by fluoroscopy. The percussion note was flat over the right base, and the breath sounds were absent. Tactile and vocal fremitus were impaired at the right base. There was a pronounced sensation of fulness on palpation of the right side of the abdomen; however, the liver edge could not be felt.

The red blood count on admission was 4,1500,000 with hemoglobin of 15 gm. The white blood count was 7,950 with 50% neutrophils, 49% lymphocytes, and 1% monocytes. In a subsequent differential the pathologist identified some of the cells of the lymphocytic series as being lymphoblasts. Subsequent differential counts showed a steady increase from 36% lymphoblasts to 100% lymphoblasts in the terminal stage. The red cell count dropped from 4,150,000 to 3,139,000 with hemoglobin of 10 gm. On four different occasions, fluid was removed from the right pleural cavity, the quantity varying from 500 cc. to 2,500 cc. The pleural fluid had a specific gravity of 1.017 with a white cell count of 12,000, 75% of these being polymorphonuclear leucocytes and 25% of these being lymphocytes; some of the latter were lymphoblasts. The total protein of the pleural fluid was 3.43 gm. The sternal bone marrow was hypercellular with 88% prolymphocytes. Roentgenograms of the chest showed a large homogenous mediastinal mass and pleural effusion on the right.

Shortly after admission, what appeared to be a superior vena cava syndrome developed. He became cyanotic, and the vessels of the neck became engorged. There was pitting edema of the chest anteriorly, and the superficial vessels of the upper abdomen and the lower chest wall became dilated. The venous pressure was 32 cm. of water, and the circulation time was 17 seconds with the use of magnesium sulfate. During hospitalization, he maintained a temperature of 101 to 102 F. and had a daily peak of 103 to 104 F. The bone marrow studies confirmed the diagnosis of acute subleukemic lymphocytic leukemia. With the realization that it would have no beneficial effect on the disease, but in an attempt to relieve the distressing symptoms of the superior vena cava syndrome, roentgen therapy was begun, 50 r

and 100 r being applied to the anterior midchest on two successive days. This was discontinued in view of the rapidly progressive disease and the lowering of the white blood count. The superior vena cava syndrome progressed rapidly. He coughed almost constantly and was dyspneic at all times. The second day after roentgen therapy, the white blood count dropped to 3,000 with 95% lymphoblasts and then gradually decreased until on the day of death the white blood count was 1,000 with 95% lymphoblasts. One week before death, he suddenly became jaundiced. The serum bilirubin was 3.75 mg. per 100 cc. as contrasted to serum bilirubin of 0.9 mg. per 100 cc. at the time of admission. He became severely jaundiced with reddish brown urine and acholic stools. Cephalin flocculation was 4+. Two days before death he showed a distinct bleeding tendency in the gums and nasal mucosa. He died 35 days after admission.

At post-mortem examination the right thoracic cavity contained 200 cc. of clear yellow fluid. The right lung was completely collapsed and airless. The edge of the liver extended to the level of the iliac crest. The left lung weighed 650 gm., and increased resistance was offered to the cutting edge. The cut surface had a smooth yellowish appearance. The consistency was less spongy and alveolar markings were less pronounced than normal. The right lung weighed 650 gm. It was compressed and airless. The anterior angle of the lung was thickened and cord-like. This entire lung was completely atelectatic. There was infiltration by a yellowish, thick, firm, homogenous material extending around the entire periphery of the compressed lung, making it almost unrecognizable as being lung tissue (figure). This homogenous material covered the entire pleural surface of the right lung. Some of this cord-like material was nodular in character. The spleen weighed 200 gm., and macroscopic examination showed no significant abnormalities. The liver was firm, swollen, and enlarged. It weighed 3,100 gm. The cut surface was homogenous with the central vein area being slightly more pronounced. A perilobular infiltration of this yellow firm material could be seen, giving the entire cut surface a yellowish color. There was tremendous dilatation of the common duct in the proximal two-thirds. The diameter of this saccular dilatation was 2 cm., and the thumb could be placed within the lumen. In the lower third portion the common duct was completely occluded by pressure from adjacent, large, firm, yellow, portal nodes. Between the nodes, there was a yellow, firm infiltrate. Extreme pressure on the gallbladder would not cause bile to flow from the common duct to the duodenum. After the dilated common duct was opened, pressure on the gallbladder caused white inspissated bile to exude from the cystic duct into the common duct. The kidneys were swollen, weighing 250 gm. (left) and 200 gm. (right). The capsule was stripped with ease, and the surface was smooth. Numerous nodes were in the mesentery, which was extremely thickened. A yellow, firm, hard, infiltrate permeated the mesentery.

Photograph showing large bronchial nodes and adjacent leukemic infiltrate.

On microscopic section, the left lung had alveoli which were thickened by a cellular infiltrate varying in extent from area to area. The cells were large and round with pale vascular nuclei resembling those seen in section through the lymph nodes and various areas of cellular infiltration. Numerous areas of hemorrhagic extravasation were present where the alveoli were completely filled with red cells. Microscopic section through the right lung could hardly be identified as lung tissue. In some areas, however, the alveoli were compressed, having lost their lumina. In most areas the tissue was unrecognizable, being composed of a mass of cells, chiefly large mononuclears, which had a very small amount of cytoplasm, large vesicular nuclei, very heavy chromatin networks, clear-cut nuclear membrane, and occasionally large nucleoli. Numerous red cells were interspersed among the white cells, and mature lymphocytes were present in small numbers. The bronchioles were compressed and had virtually lost their lumina.

The pericardium showed very sparse, although in some cases more focal and pronounced, infiltrate of cells resembling those described in the lung.

The hematopoietic elements in the marrow were virtually replaced by a single type of cell, a large lymphocyte similar to those previously described. Small lymphocytes were present also, and there was a sprinkling of red cells between them. The cells were not closely packed. The blood sinuses were virtually empty, only a few red and white cell precursors being seen. This implied failure of delivery of the white cells into circulation and explained the paucity of cells in the peripheral blood.

The lymph node structures were completely obliterated by a mass of large mononuclears, similar to those previously described in the lungs. Some of the nuclei, however, were not completely round but were somewhat bizarre or spindle shaped. Numerous areas of hemorrhagic extravasation were present. A thin fibrous reticulum could be seen ramifying among groups of cells. There was little or no involvement of the spleen by leukemic cells which were to be seen only in the blood vessels. The splenic pulp itself appeared normal except for dilated sinusoids, and the architecture was not obliterated. The malpighian corpuscles were fairly normal in size and number. In the small intestines in certain areas the villi were necrotic, and the mucosa and submucosa were richly infiltrated with a dense mass of lymphocytes. These were mainly small lymphocytes and did not appear to be of the lymphoblastic type seen in other organs and in the infiltrated areas. The extent, however, was much greater than that observed in Peyer's patches. There were no significant abnormalities seen in the kidneys except for several areas of interstitial infiltration with cells resembling those previously described, these being just under the renal capsule.

COMMENT

Obstruction of the common bile duct by enlarged portal nodes is uncommon. When it does occur, it is nearly always caused by tuberculosis, Hodgkin's disease, or lymphadenitis.[1] Obstructive jaundice due to enlarged portal lymph nodes caused by leukemia is extremely rare.[2]

SUMMARY

A case of acute subleukemic leukemia is presented which shows several interesting and unusual features: (1) leukemia with a normal white cell count at admission; (2) leukopenia during nearly all the hospital course; (3) superior vena cava syndrome, and (4) jaundice due to obstruction of the common bile duct by enlarged portal nodes, with tremendous dilatation of the common duct.

PULMONARY CHANGES FOLLOWING CHOLECYSTECTOMY

Isadore Rudnikoff, M.D.
and
Courtenay I. Headland, M.D., Yonkers, N. Y.

The incidence of pulmonary complications following abdominal surgery has long been a matter of concern to the physician and patient. Although scores of manuscripts have been written about various phases of the subject, no single work was found which described the clinical and roentgenologic changes following cholecystectomy. It was our impression that these were of sufficient significance to warrant investigation. This study was thus undertaken with a hope of obtaining data which might be of practical importance.

A review of the related literature over a period of 20 years was undertaken. It revealed certain pertinent information. In an analysis of 23,000 general surgical cases, Eliason and McLaughlin [1] reported an incidence of 1.38% of postoperative pulmonary complications. Taylor and his co-workers [2] reported 1.2% of lung abnormalities in a series of 12,349 cases. King [3] in 1933 stated that between 35 and 46% of patients undergoing surgery of the stomach, duodenum, and biliary tract showed signs of bronchitis, pneumonitis, and atelectasis. That same year Prinzmetal and others [4] stressed the importance of pulmonary subventilation after surgery in the upper abdomen and discussed the mechanisms involved. Faulconer and his associates [5] found that in about 8% of patients having operations on the upper urinary tract, atelectasis developed in the contralateral lung. They felt that this was owing to the lateral position the patient assumed during operation. It was their impression, also, that the method of anesthesia did not materially affect the end results. Stringer,[6] in a series of 55 patients on whom partial gastrectomy had been done, noted that 26 showed abnormal postoperative roentgenologic signs. Of the latter number, 13 had signs of lobular, partial, or massive atelectasis. He x-rayed these individuals in the supine position immediately, four, and 24 hr. after operation. No signs were noted in the immediate postoperative films, but roentgenologic changes appeared in some in four hours and in others in 24 hr. Other pathological changes noted were interpreted as bronchopneumonia, bronchitis, and collapse with effusion.

Recently, two significant works on this general subject made their appearance. In the first, Dripps and Deming [7] reported the rate of occurrence of postoperative atelectasis and pneumonia in two series of cases in which upper abdominal operations had been performed. In the earlier group of 250 patients they found the incidence to be 11% for subjects receiving inhalation anesthesia and only 4.2% in those given spinal anesthesia. The later group consisted of 900 patients. These were subjected to all precautions in order to avoid postoperative pulmonary complications. The incidence in those given spinal anesthesia remained essentially unchanged, whereas after inhalation anesthesia the rate decreased to 4.1%. The use of narcotics was kept to a minimum; codeine was used for the relief of pain; the use of abdominal binders was avoided, and small amounts of adhesive and light gauze dressings were used. Other precautionary measures included early mobilization, suction of the nasopharynx, and prophylactic antibiotics. Local nerve blocks were employed to relieve pain and allow for greater respiratory movements. They concluded that, unless a meticulous and comprehensive preventative program was followed, regional and spinal anesthesia are preferable from the standpoint of pulmonary complications.

The second paper, by Swank and Smedal,[8] presented a study of pulmonary atelectasis in stuporous states. They observed pulmonary atelectasis, bronchopneumonia, and related phenomena during continuous deep amobarbital (amytal®) sodium narcosis in young soldiers and found the incidence to be as high as 65%. They x-rayed the chests in the supine position and found that the lesions disappeared within from a few to 24 hr. Aside from the temporary nature of the roentgenologic changes, they felt that these changes could easily have been confused with atypical pneumonia.

MATERIAL AND METHOD

The clinical material consisted of 40 consecutive patients who were to have cholecystectomies only. These individuals were drawn from the ward and private services of six different surgeons and included several age groups. All roentgenograms of the chest were taken with the patients in the upright position and at a target distance of 2 m. The technique was standardized so that films of comparable densities were obtained. The roentgenograms were taken within 24 hr. before operation, on aproximately the fourth postoperative day, and at the time of the patient's discharge from the hospital. In addition to the x-ray studies, certain other pertinent data were recorded. These included the patients' age and sex, type of habitus, history of previous pulmonary infections, methods of anesthesia, and duration of operation. The clinical course and degree of ambulation in the postoperative period were especially noted.

FINDINGS

Of the 40 patients included, 30 were women and 10 were men. Of these, 37 received a combination of nitrous oxide, ether, and oxygen, with or without thiopental (pentothal[s]) sodium for induction; and three were given spinal anesthesia. The time for operation varied from 35 min. to three hours, with an average of one hour and 10 min. All patients were taken out of bed between the second and sixth postoperative day, the mean here being 3½ days. Discharge from the hospital usually took place between the eighth and 12th days.

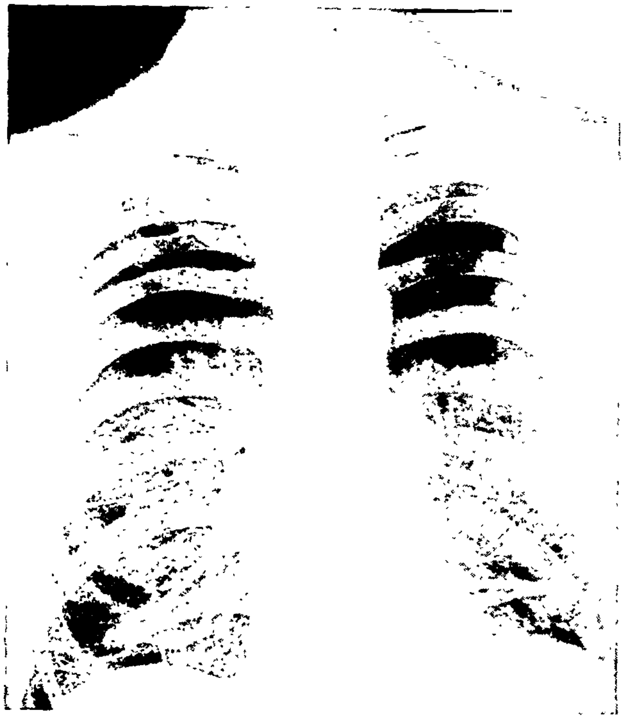

Fig. 1.—Illustration of platelike atelectasis.

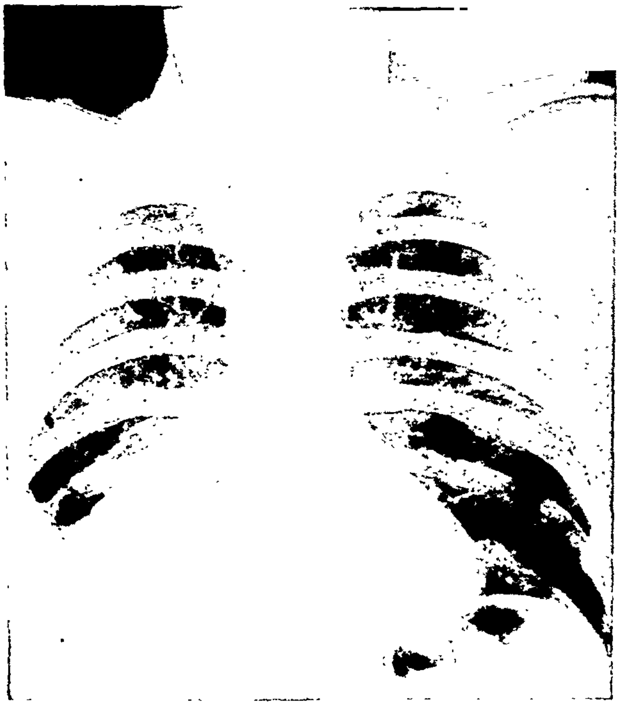

Fig. 2.—Illustration of extensive atelectasis.

Roentgenograms of the chest before operation were normal in all the 40 patients. On the fourth postoperative day, 28 of these, or 70%, showed changes, not previously present, in the roentgen appearances. These were interpreted as platelike atelectases, patchy or extensive atelectases, or bronchopneumonias. These three types are illustrated in Figures 1, 2, and 3. It was further noted that the lesions occurred bilaterally and either on the right or left side. The former predominated in a ratio of 3 to 2.

Although 28 patients showed deviations from the normal in their postoperative x-rays, 10 (37%) of these (or 25% of the entire series) exhibited symptoms and signs of sufficient clinical significance to require additional treatment. The importance of the roentgenograms at the time of discharge was demonstrated adequately when such observations revealed that seven patients showed residual atelectases or pulmonary infiltrations on the day they left the hospital. The only death resulted from massive pulmonary embolism. An analysis and summary of these data are presented in the table. The relationship of sex to incidence is not shown because seven of 10 male patients and 21 of 30 female patients (both 70%) showed postoperative roentgenologic changes in the lungs.

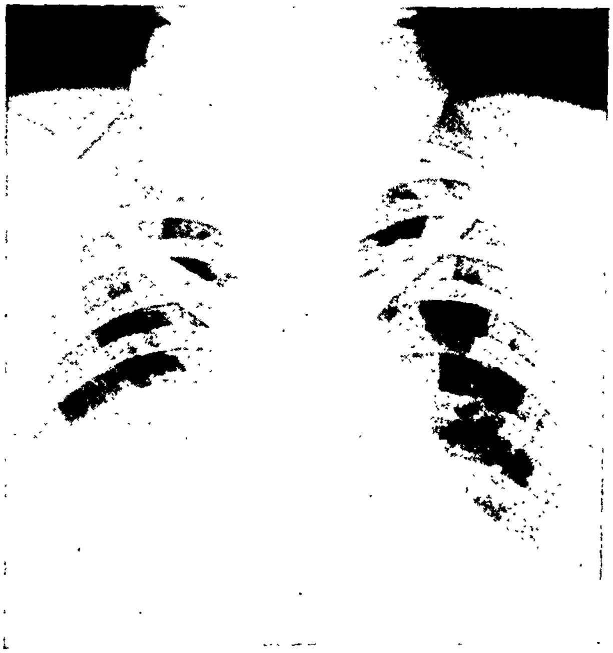

Fig. 3.—Illustration of pneumonic infiltrations.

COMMENT

It is difficult and at times hazardous to evaluate and interpret changes which occur in roentgenograms of the chest taken after operation. The importance of the postoperative interval in relation to pulmonary findings cannot be overemphasized. It has been our impression and experience that almost 90% of patients undergoing surgery in the upper abdomen will exhibit pulmonary signs in the first 24 hr. following the operation. Physical findings during this period include diminished breath sounds at the lung bases, elevated diaphragms, and showers of moist, crepitant, and sonorous rales. Roentgenograms taken during this time usually reveal diminished aeration of the bases of the lungs, symmetrical or asymmetrical elevation of the diaphragms, and atelectasis. Many of these findings are transitory and tend to disappear within the first 24 hr. For these reasons, the authors felt that every effort should be made to eliminate these purely evanescent manifestations. In this way, the lesions which appeared in the lungs would have greater clinical significance. It was felt that this could be accomplished by avoiding the use of roentgenograms made in the supine position or by portable x-ray apparatus, and by delaying such studies until the fourth postoperative day and at the time of discharge.

The various types of lesions which were observed in either or both lungs roentgenographically were, at times, difficult to interpret with accuracy. Some suggested bronchopneumonia; others, different degrees of atelectasis. This situation served again to emphasize the great need for a standard nomenclature in reference to the roentgenologic interpretation of atelectasis and pneumonia. The frequent appearance of linear shadows at the bases of the lungs were of considerable interest. These platelike or disklike atelectases were first described by Fleischner in 1936.[9] He attributed them to restrictions in respiratory excursions and plugging of the smaller bronchiolar radicles with tenacious mucus. He noted their occurrence during and after upper abdominal disease or operations, in contusions of the chest wall, and in other states in which motions of the thoracic cage were interfered with. Actually such areas of atelectasis are the result of physical and mechanical phenomena.

TABLE 1.—*Analysis of Data*

Age Groups	No. of Cases	Positive Post-operative X-Rays	Significant Pulmonary Morbidity	Residual Lung Findings at Discharge
10-19	1	1	..	..
20-29	2	1	..	..
30-39	3	2	..	..
40-49	10	4	2	2
50-59	15	12	6	4
60-69	7	6	2	1
70-79	2	2	..	..
Total	40	28 * or 70%	10	7

* Sixteen patients had bronchopneumonia, and 17 had atelectasis (five had both).

There has been a tendency on the part of some roentgenologists to minimize the importance of platelike atelectases and to suggest that they have little clinical significance. Other authors,[10] however, have emphasized their significance not only because they may be a source of spreading atelectasis but also because of the possibility of superimposed complicating infections in such areas. At least one case [11] was recorded wherein the diagnosis of platelike atelectasis was made, which subsequently proved to be linear metastases. Further emphasis on the latter point of view was made by Fleischner, Hampton, and Castleman.[12] They described these and other lesions in a thorough study correlating roentgenographic and microscopic findings. In discussing the differential diagnoses of linear and band-shaped shadows in the lungs, they included interlobar pleurisy, atelectases, healed infarcts, and scarring from old destructive lesions. It was their opinion that many of these are so similar in appearance as to prevent differentiation by the roentgenologist.

Our studies have indicated that the incidence of pulmonary complications as seen roentgenographically after cholecystectomy, and probably other operations in the upper abdomen, is higher than has previously been reported in the literature. The presence of residual abnormalities in the lung roentgenograms in a moderate number of patients at the time of discharge is, we believe, of considerable significance. It would be of interest to study a large series of such postoperative cases in this respect. It might offer some explanation for the prolonged period of debility in some persons.

While it is difficult to translate roentgenologic findings into clinical syndromes, it must be stressed that as long as abnormalities are found in the postoperative chest roentgenograms, potential sources of spreading atelectasis and superimposed infections exist. It is of considerable importance, therefore, to exercise every meticulous precaution during the postoperative period. It is desirable to avoid excessive sedation and narcosis before and after operation. Restrictive dressings and covers serve only to interfere with the normal excursions of the chest wall. Dehydration, because it causes bronchial secretions to become thicker and more tenacious, must be overcome quickly. Finally, the need for early mobilization whenever possible must be recognized.

SUMMARY

The postoperative pulmonary findings in 40 consecutive patients undergoing cholecystectomy are presented. The clinical and roentgenologic implications are discussed, and the relevant literature is reviewed.

Significance of Personal Problems.—There are two sides to the doctor-patient relationship. Not only must the patient feel confident of the doctor's desire and ability to help him, but the doctor must feel a sincere interest in the patient as a person and in his problems. This interest must be sufficiently deep to be sustained over long periods and to create a determination to see the patient through his troubles without passing judgment or feeling resentment in regard to behavior involving ethical or moral questions, and without being disturbed by unattractive traits of personality.—G. Canby Robinson, M.D., The Significance of Personal Problems in the Understanding and Treatment of Illness, *Bull. Johns Hopkins Hosp.* April, 1951.

ANTICOAGULANTS IN ACUTE FROSTBITE

Frank V. Theis, M.D., William R. O'Connor, M.D.
and
Frederick J. Wahl, M.D., Chicago

The treatment of acute frostbite has been advanced greatly by experimental investigations[1] on the pathologic physiology of this injury during the last war. This work was stimulated by the frequent occurrence of frostbite in the armed forces[2] and the unsatisfactory results of the accepted forms of treatment. Lange,[3] Friedman,[4] and Shumacker[5] then demonstrated experimentally that anticoagulants in acute frostbite prevented development of thrombosis and gangrene. In civilian practice the occurrence of frostbite is, as a rule, uncommon, so that series of clinical results with the use of anticoagulants have not been reported. However at the Cook County Hospital in Chicago, 30 patients with frostbite were admitted and treated during the winters of 1949 and 1950; 14 of them had acute frostbite and were treated with effective anticoagulant therapy, in addition to the treatment previously used. The purpose of this report is to present the results of such treatment.

SELECTION OF CASES

Of the 30 patients with severe frostbite who required admission to the hospital during the winters of 1949 and 1950, only 14 who were exposed to the cold within 16 hours before treatment was initiated were treated with anticoagulants. The average duration of exposure was 10 hours. When the exposure occurred days or weeks prior to admission and gangrene or necrosis of tissue was already present, it was obvious that anticoagulants would be of no value. At the time of exposure, the temperature ranged from 5 to 20 F. However, the severity of the frostbite is dependent not only on the temperature, duration, and type of exposure to cold, but also on the wind velocity, the humidity, and the general condition, age, and individual susceptibility of the patient to cold. The duration of exposure was difficult to ascertain when patients had been found lying on the sidewalk, frequently in an alcoholic stupor and unable to recall the immediate past events. One patient had been shoveling coal without gloves for seven hours. All the patients were men, and the average age was 54, their ages varying from 35 to 80.

As usual, the extremities are affected to the greatest extent; in order of frequency, the hands, feet, face, and in two cases all four extremities were severely involved. These latter two patients, on admission, were in profound shock with unobtainable blood pressure and pulse. Paralysis or paresis of the toes were noted in three cases, of the fingers in two cases, and three other patients complained of paresthesias and hypesthesia.

METHODS OF TREATMENT

Anticoagulant therapy was started within one to two hours after admission. Fifty milligrams of heparin sodium was given intravenously as soon as possible and was given every four hours for 36 to 48 hours. The clotting time was determined by the two tube modification of the Lee-White method. In addition, all patients were given 200 to 300 mg. of bishydroxycoumarin (dicumarol®) as soon as they were able to swallow. Daily prothrombin levels determined the subsequent doses of bishydroxycoumarin. Attempts were made to maintain an effective prothrombin level of 10 to 20% of normal; the usual duration of treatment was 10 days. Later it was felt that heparin sodium should be given every three hours to maintain a prolonged clotting time above twice the normal level.

The routine treatment employed previously was continued in this series of cases so that the beneficial effects of the anticoagulant therapy might be permitted. This included bilateral lumbar paravertebral blocks on four patients early in the series, but later these were discontinued because of the hazard of deep needle punctures in the presence of anticoagulant therapy. One patient received tetraethylammonium chloride. Blood and plasma transfusions were necessary in four patients to combat shock. Local treatment of the affected extremities consisted of gentle cleansing with soap and water, alcohol, and the application of sterile dry or petrolatum gauze pressure dressings. Thawing was done at room temperature (no additional heat and no cooling). Penicillin was given to all patients to combat infection. The principles for treatment of acute frostbite are as follows:

1. TO PREVENT SHOCK

    Watch blood pressure, blood counts, proteins, and hematocrit.

    Give blood or plasma transfusion, as indicated or available.

    Pressure bandages (ace® or tetra®) are applied to extremity to well above expected level of frostbite. Extravasation of plasma due to edema and blistering may be minimized. The pressure dressings need not be removed for 10 to 12 days unless for sepsis or for other special reasons.

    Oxygen therapy may be required for severe generalized frostbite.

2. TO PREVENT INFECTION

Strict surgical asepsis to frostbitten area is carried out. Cleanse part, and apply sterile dry or petrolatum gauze dressings. No massage or snow is to be applied.

Antibiotics are administered daily for at least a few days or until oral temperature is normal. Antitetanic serum is given as indicated.

3. TO PREVENT INTRAVASCULAR CLOTTING AND GANGRENE

Thaw frostbitten extremity at room temperature only. No external heat or cold is to be applied.

Anticoagulant therapy must be started within 16 hours after thawing begins.

Heparin sodium, 50 mg. intravenously, is to be given as soon as possible and repeated every three hours until effective prothrombin deficiency is obtained with bishydroxycoumarin therapy.

Bishydroxycoumarin is started as soon as patient can swallow and blood prothrombin level has been obtained.

Initial dose is 300 mg. and subsequent daily doses are decided on after prothrombin level is determined.

Effective prothrombin level is between 10% and 20% of normal. Continue for eight days. No walking or trauma to feet or hands.

RESULTS

When compared to previous years, the results of our present routine treatment of acute frostbite with anticoagulant therapy were far more satisfactory. Only one patient required amputation of a finger, although considerable loss of tissue was usually expected. One patient had persistent dependent edema and paresthesia. One death due to massive retroperitoneal hemorrhage occurred after successive lumbar blocks, probably caused by the concomitant use of anticoagulant therapy. This case has been reported elsewhere.[6] The average period of hospitalization was 42 days and the longest 270 days (case 1); many patients who were not treated with anticoagulants required hospitalization for eight months to a year or more. The following two cases are described to illustrate the results of treatment in acute frostbite with anticoagulant (case 1) and without anticoagulants (case 2).

REPORT OF CASES

CASE 1.—Mr. P. B., 50, a Negro man, was brought to Cook County Hospital on Jan. 29, 1949, in an unconscious condition after prolonged exposure to cold. He had been under the influence of alcohol and had slept for about eight hours in a gangway when the temperature was about 10 F. All four extremities were "ice cold," stiff, and solid to touch. The dorsalis pedis and radial artery pulsations were not palpable, and the patient was considered to be in an extreme condition. Blood pressure was unobtainable on admission, and the heart beat was weak. Rectal temperature was too low to be recorded on a clinical thermometer.

Within one hour after admission and exposure to room temperature, both radial artery pulsations were weakly palpable, and the blood pressure was 108/70. Whole blood, 500 cc., was administered intravenously and was followed with 1,000 cc. of 5% dextrose solution. Heparin sodium, 50 mg., was given intravenously, and this was repeated every four hours for three days. The initial prothrombin level was 95% of normal, and eight hours after the patient's admission, bishydroxycoumarin treatment was started with a 300 mg. dose the first day and 200 mg. doses the second and third days. Within 72 hours the prothrombin level reached 31% and was further reduced to 12.5%. Bishydroxycoumarin was continued for 11 days. Penicillin was given in 300,000 unit doses every four hours for 14 days, at which time it was replaced by sulfadiazine, given orally.

The upper and lower extremities were treated locally with soap, water, and alcohol and the application of sterile petrolatum gauze pressure dressings. The initial dressings on the legs had not been applied high enough so that extensive bullae developed above the level of the dressings. Reapplication of the pressure dressings to extend above the knees prevented further development of bullae (fig. 1).

Except for a low grade fever that occasionally spiked to 103 F., the patient made a surprising recovery. He regained consciousness in eight hours. Pronounced fibrous tissue formation in the fingers and toes gradually improved with physiotherapy treatments, and only the right fifth finger required amputation, though all fingernails and toenails came off. He was discharged from the hospital on Sept. 20, 1949. The long period of hospitalization was due largely to the physiotherapy treatment that was required for the fibrous tissue formation in the extremities. Some residual fibrosis and swelling of the hands and feet were present when the patient was last seen one year after the frostbite.

It is impossible to predict the extent of gangrene and necrosis that would have developed if anticoagulant therapy had not been used. However, from our previous experience and from our observations on patients who were admitted too late for anticoagulant therapy to be used, it could be assumed that both hands and both feet would have become gangrenous and required amputation. The extreme fibrosis that occurred in the hands and feet and the fingers and toes is attributed to the failure of heparin sodium given every four hours to maintain continuous anticoagulation. Accordingly, heparin sodium is now given at three-hour intervals.

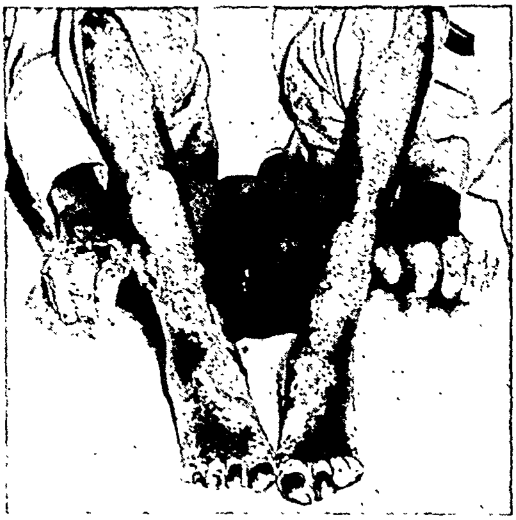

Fig. 1 (case 1).—Severe frostbite of all four extremities treated with anticoagulants within one hour after patient's admission to the hospital. Appearance at three weeks shows fibrous thickening of the digits and contracture deformities. Improvement followed physical therapy treatments. Gangrene of the right fifth finger required amputation later.

CASE 2.—Mr. W. H., 49, a white man, was admitted to the hospital four days after exposure to temperature of 0 F. for two hours. Although wearing gloves, his hands became cold, white, numb, and "frozen." He had been drinking, and friends at a gasoline station rubbed snow on the hands for "some time" and then took him to a local hospital. His hands became blue, swollen, and oozing to the level of the wrists. Blisters had been present. The feet were only slightly reddened and painful. Diagnosis on admission was "superficial gangrene." In the course of three weeks both hands to the level of the wrists became black and gangrenous (fig. 2). Bilateral amputations were required later.

6. O'Connor, W. R.; Preston, F. W., and Theis, F. V.: Retroperitoneal Hemorrhage Following Lumbar Sympathetic Block During Treatment with Dicumarol, Ann. Surg. 131: 575, 1950.

It is not possible to predict the course that this patient would have had if our present regime for the treatment of frostbite could have been used. However in the fourteen cases treated with anticoagulants, such a tragic result did not occur despite apparently equally severe frostbite. In patients treated with anticoagulants no deep gangrene developed.

COMMENT

The confusion that has existed in the principles of treatment of acute frostbite seems to be clarified somewhat by recent investigations on the pathologic physiology of the injury. Ungley and Blackwood [7] and Ungley and others [8] consider the primary tissue damage a peripheral vasoneuropathy which produces a reduced blood supply, edema, and extravasation of blood. Therefore, they direct therapy to reduce the swelling by pressure bandages and to counteract the deficient oxygen supply; local tissue metabolism is diminished by prolongation of the period of thawing when the injured part is cooled. Another group, Greene,[9] Siegmund,[10] Friedman,[4] and Shumacker,[5] regards as principal damage the formation of thrombi in the arterioles and capillaries. These authors advise prompt restoration of circulation and prevention of thrombi by anticoagulant therapy.

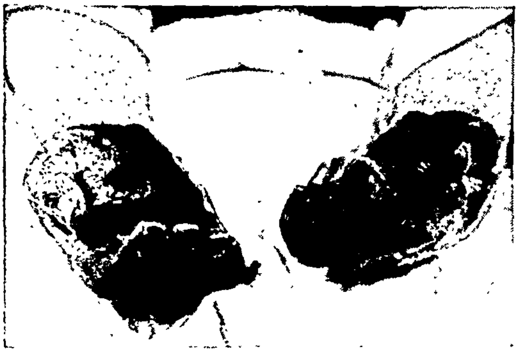

Fig. 2 (case 2).—Severe frostbite of hands before anticoagulant therapy was being used. Appearance at three weeks shows demarcation of dry gangrene of both hands which later required amputation.

Lange and his associates [3] have contributed greatly to our present knowledge of the physiology and pathology of acute frostbite in experimental animals by the use of fluorescein test, the capillary microscope, and histologic studies. They showed alteration of the blood circulation in the tissues during exposure to cold. Under the capillary microscope just before freezing occurs, the red cells are seen to collect in irregular clumps or masses with plasma in between until finally the circulation comes to a complete halt. At this stage, the fluorescein test shows a complete absence of dye from the affected tissues. This persists for about one hour after exposure and indicates a vasoconstriction and circulatory stasis. Clinically the limb has a white cadaverous appearance, which follows the initial blanching and pink color on exposure.

As thawing occurs, the blood flows again and the red cells gradually resume their discreteness. At this stage there is vascular engorgement, increased blood flow through the limb, and an increased capillary permeability. The fluorescein test shows hyperfluorescence in these tissues. As plasma rapidly diffuses into the interstitial spaces, the red cells silt up in the capillaries, forming a sludge that contains some platelets but little or no fibrin. These are not true fibrin thrombi but are called "agglutinative thrombi." Clinically the part becomes intensely red, rapidly swollen, and warm. Blebs and bullae develop, which contain a straw-colored or blood-tinged fluid with a protein content similar to that of plasma. Loss of sensation, especially to pin prick, heat, and cold, appears.

In the final stage, within 24 to 48 hours, a dense fibrin clot forms in the blisters. This same process probably takes place in the interstitial spaces after the exudation of plasma; as a result, new formation of fibrous tissue and scarring and damage to the muscles and nerves occur. Three to eight days after the exposure the agglutinative thrombi undergo hyalinization, resulting in occlusive masses. The fluorescein test will show patches of nonfluorescence, and, clinically, dry-black areas of gangrene are evidence of the vascular obstruction. These observations indicate that the fundamental lesions in acute frostbite are intravascular.

Since gangrene subsequent to frostbite appears to be due to the occlusive red cell thrombi, the early use of effective anticoagulant therapy is suggested to interrupt the chain of events. Heparin sodium is known to interfere with the adhesiveness of agglutinative thrombi, and this may prevent thrombosis and gangrene in acute frostbite. Anticoagulants also preserve the resorbability of the interstitial fluid, thereby preventing secondary fibrous tissue formation. This is evidenced by the absence of clot formation in blisters when adequate anticoagulant therapy is maintained.

Anticoagulant therapy to be beneficial in frostbite must be given promptly after exposure and in adequate and effective amounts. Shumacker,[5] on the basis of animal experiments, believes that anticoagulant therapy is of greater value in the milder forms of frostbite; the more prolonged the coagulation time, the greater will be the effectiveness of this treatment in prevention of gangrene. He also feels that the drugs are of value only when treatment is started within 16 hours after exposure. It is impossible to give absolute criteria for the effectiveness of anticoagulants in prevention or limitation of the extent of gangrene in frostbite. From experimental results, Shumacker, however, believes that anticoagulant therapy is a valuable adjuvant in prevention of frostbite necrosis.

SUMMARY

Fourteen of the 30 patients with acute frostbite admitted to Cook County Hospital of Chicago during the winters of 1949 and 1950 were treated with anticoagulants. The results were most gratifying, as only one of the treated patients required local amputation of a finger. The duration of hospitalization has been appreciably reduced, and the patients returned to normal activities more quickly.

[9] Greene, R.: Immediate Vascular Changes in True Frostbite, J. Path. & Bact. 55: 259, 1943. Cold in Treatment of Damage Due to Cold, Lancet 2: 695, 1942.

[10] Siegmund, H.: Pathologisch-Anatomische Befunde bei Örtlichen Kälteschädigungen mit Berücksichtigung der Spätschaden, Zentralbl. f. Chir. 70: 1558, 1943. Zur Pathogenese und Pathologie von örtlichen Kälteschädigungen München med. Wchnschr. 89: 827, 1942.

Anticoagulant therapy was instituted shortly after admission. Heparin sodium was given every three or four hours for maintenance of an elevated clotting time and until adequate effect with bishydroxycoumarin (dicumarol®) was produced. Other treatment is important and consists of combat of shock with blood and plasma infusions, thawing of the involved areas by exposure to room temperature only, cleansing and application of sterile dry or petrolatum gauze pressure dressings, and employment of antibiotics to combat infection. A report of the pathologic physiology and the experimental background of our present knowledge of acute frostbite has been presented. Case histories are abstracted to illustrate the treatment as now used and the results of treatment of acute frostbite with and without anticoagulant therapy. Adequate anticoagulant therapy in the acute stage of frostbite is of great value in reduction of the incidence and extent of gangrene and the period of disability.

CLINICAL RESPONSE OF RHEUMATOID ARTHRITIS TO POSTPARTUM PLASMA

A TWO YEAR STUDY

Louis W. Granirer, M.D., Jamaica, N. Y.

The purpose of this paper is to summarize the clinical observations of eight patients with rheumatoid arthritis treated with postpartum plasma over a period of two years. These patients have now been followed long enough to permit an appraisal of this form of therapy.

A preliminary report of some of the earlier effects of postpartum plasma on these patients was made in a previous presentation.[1]

METHOD OF STUDY

This report covers the period from February, 1948, to May, 1950, and is based on observations of eight patients with rheumatoid arthritis. Only patients showing a chronic but active course of the disease were selected for treatment. All the patients had a disabling polyarticular rheumatoid arthritis graded as severe or very severe and were bedridden or confined to a chair. Patients were observed for a control period of at least two weeks prior to institution of therapy. In addition to the usual clinical observations, the total red and white blood cell count, differential count, erythrocyte sedimentation rate (Westergren), blood cholesterol and serum proteins were determined at frequent intervals. X-rays, blood pressure, and body weight were recorded routinely. Motion pictures were taken of most patients before, during, and after the use of postpartum plasma.

Table 1 contains certain data concerning the eight patients. Ages varied from 48 to 63 years. The duration of the arthritis was from 6 mo. to 18 years. Most of the patients walked with difficulty and required help. Subcutaneous nodules below the olecranon process were present in four cases. The classification of stages of rheumatoid arthritis and the criteria for therapeutic response of rheumatoid activity adopted by the New York Rheumatism Association were used in evaluating the results that are described in table 1.

Pooled postpartum plasma was administered intravenously in doses of 250 cc. once a week. In general, no toxic reactions were encountered other than an occasional attack of urticaria that responded promptly to antihistamine therapy. To provide controls, plain plasma transfusions in doses of 250 cc. each were administered weekly to a similar group of patients. No clinical or biochemical benefit occurred. When postpartum plasma was replaced by plain plasma symptoms were usually worse within a few days.

CLINICAL RESPONSE

Doses of less than 200 cc. of postpartum plasma were ineffective in producing a clinical response. It was soon noted that an improvement usually occurred between the fourth and sixth treatment. The average patient required 6 to 8 pt. (2.8-3.8 L.) of postpartum plasma before a remission took place.

The improvement was gradual, with relief of stiffness and decrease in pain, joint swelling, and inflammation. One patient with psoriatric arthritis has been symptom-free 18 mo. Four patients have maintained their improvement after treatment was discontinued 12 mo. There were no toxic effects and no cases of homologous serum hepatitis. Some patients required a larger amount of plasma given over a longer period of time before a beneficial effect was noted. The beneficial effect of postpartum plasma in a patient with severe asthma was observed during the course of treatment, suggesting an effect on the immune mechanisms underlying both conditions.

Four patients had typical subcutaneous nodules below the olecranon process. With treatment, these disappeared completely.

A dramatic effect on flexion contractures of recent origin was seen in two patients.

Analysis of the chemical determinations is demonstrated in table 2.

Two patients failed to respond. In retrospect, it appears that in both the course of therapy was too short (six treatments) and warrants no conclusion, since the therapeutic trial was obviously of insufficient length.

COMMENT

In the present study the number of patients treated with postpartum plasma was small. The results, however,

---

Read before the Meeting of the New York Rheumatism Association, May 10, 1950.

From the Department of Medicine and the Arthritis Clinic, Queens General Hospital.

[1] Granirer, L. W.: Read before Seventh International Congress on Rheumatic Diseases, New York, June 1949, to be published.

over a two-year period showed a definite amelioration of the clinical manifestations. Although there was not always a complete disappearance of symptoms, relief was greater than with any preceding therapy. The patients experienced an improved sense of well-being, an increase in appetite, strength, and gained considerable weight.

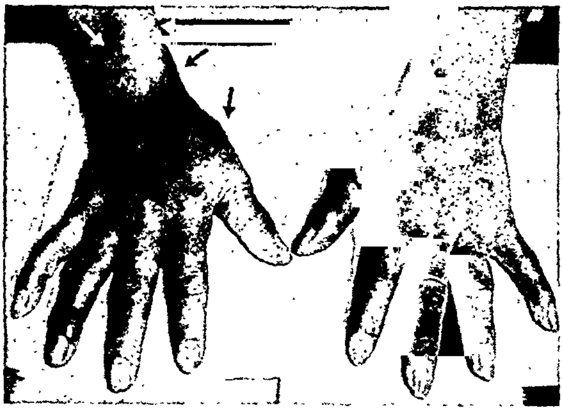

Fig. 1.—Hands of patient before treatment with postpartum plasma. Note swelling of the wrists and finger joints.

Associated with the clinical improvement, there was a return to normal of the serum albumin, globulin, and hemoglobin. Sedimentation rates remained elevated in most of the patients and were not found to be a dependable sign as to the clinical progress. The plasma cholesterol usually rose above the pretreatment levels as the patients improved.

On cessation of therapy a return of symptoms required from six weeks to 12 mo. The longest remission was 18 mo. In general, the return of symptoms was slow, and they never reached the former degree of severity. Resumption of postpartum plasma therapy was always effective when there was a recurrence of symptoms. Subcutaneous nodules completely disappeared, indicating that the antirheumatic substance or substances in postpartum plasma have a definite effect on the mesenchyme. In my experience postpartum plasma therapy distinctly changes the course of the disease. It shortens the activity of the illness and dramatically reduces the disability.

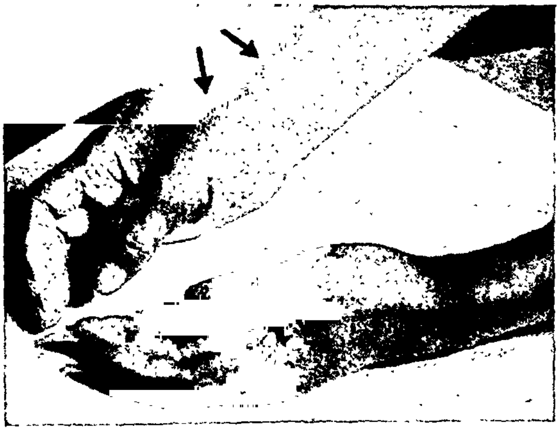

Fig. 2.—Hands of same patient, again before treatment; unable to close hands.

As a rule, no side effects were noted. There was no rise in blood pressure, blood sugar, or other undesirable chemical disturbance. One patient in whom urticaria developed after treatment responded well to antihistamines. Another complained of sensitive breasts. Ascheim-Zondek tests were negative in all cases. There were no complaints of acne, hirsutism, amenorrhea, moon face, pigmentation, or striae. Postpartum plasma almost uniformly possesses a greenish tint (pea soup) that is homogenously distributed; the albumin and globulin are low.[2] Postpartum plasma cholesterol is also low, and the phospholipids never exceed the upper limits of normal.[3]

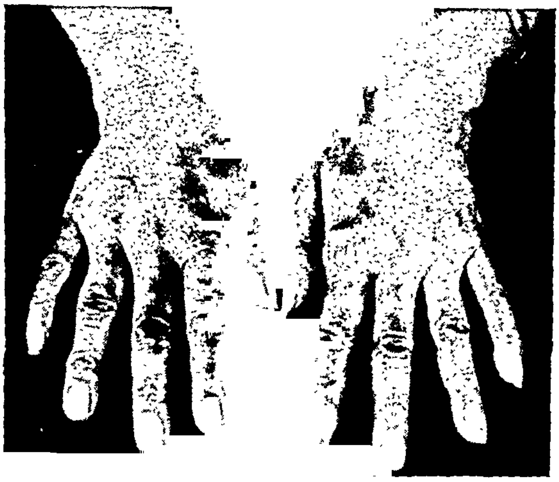

Fig. 3.—Hands of patient after treatment with postpartum plasma; disappearance of effusion and joint swelling.

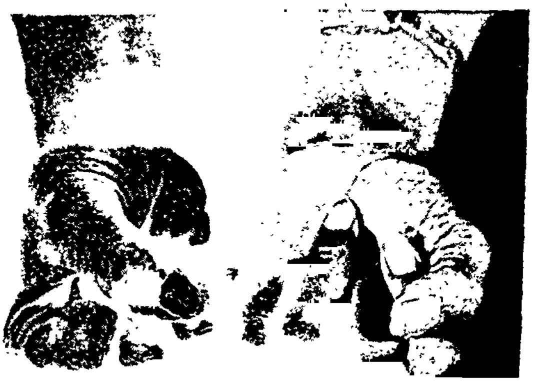

Fig. 4.—Hands of patient after treatment; patient can now completely close her hands.

The result of this preliminary study over a two-year period indicates that postpartum plasma is an effective mode of treatment for rheumatoid arthritis. Administration of the plasma over a long period can be well tolerated. Once a remission occurs treatment need not be taken continuously. Relapses are usually mild and gradual and respond well to further therapy. Postpartum plasma is an available antiarthritic agent, and its production is neither difficult nor costly. Although complete relief was not achieved in all cases, the results obtained with postpartum plasma, on the whole, were as dramatic as any recorded for cortisone or pituitary adrenocorticotropic hormone (ACTH).

---

[2] Granirer, L. W.: A Study of the Albumin-Globulin Content In Postpartum Plasma, Science 3:204, 1950.

[3] Granirer, L. W.: A Study of the Lipids In Postpartum Plasma: Its Use in Rheumatoid Arthritis, Surg., Gynec. & Obst. 91:591-592 (Nov.) 1950.

ADDENDUM

Since July, 1950, seven patients resistant to previous cortisone and pituitary adrenocorticotropic hormone (ACTH) therapy have shown an excellent response to postpartum plasma. In this series there were five patients with severe rheumatoid arthritis, one patient with exfoliative dermatitis and arthritis, and one with Still's disease.

CONCLUSIONS

In the present study the number of patients treated was small, and it is realized that the results obtained in this initial study will have to be confirmed.

1. Pooled postpartum plasma produced a gradual and sustained remission in rheumatoid arthritis.

2. Remissions were observed to last from six weeks to one and one-half years.

3. The chemical abnormalities present in the disease were restored to normal.

4. Patients gained from to five to 30 lb. (2,200-13,600 gm.).

5. An improved sense of well-being, a better appetite, increased vigor, strength, and amelioration of joint pain and swelling were routinely observed.

6. There was no relationship between the sedimentation rate and the clinical improvement.

7. In more than 500 postpartum plasma treatments there were no instances of homologous serum hepatitis.

8. Unlike either pituitary adrenocorticotropic hormone (ACTH) or cortisone, postpartum plasma had no side effects; treatments were administered only once a week.

TABLE 1.—*Before and After Treatment with Pooled Postpartum Plasma*

Case	Age	Rheumatoid Arthritis Duration and Degree	Extent of Involvement	Complications	Weekly Dose	First Improvement Noted	Total No. of Treatments	Duration of Remission	Grade of Response	Comments
1	48	3 yr.; stage 3 (severe)	Shoulders, hands, wrists, elbows, knees, ankles, feet; bedridden	Alopecia	250 cc.	4 treatments	14	4 mo.	Grade 2 (marked)	Subcutaneous nodule below elbow disappeared after 9 treatments; hair on scalp returned; gained 19 lb.
2	42	9 yr.; stage 3 (severe)	Fingers, wrists, elbows, shoulders, hips, knees, ankles; bedridden; 1943, severe nephritis after gold salts	Cholecystectomy	250 cc.	5 treatments	16	14 mo.	Grade 2	Large subcutaneous nodule below both elbows disappeared after 6 treatments; gained 20 lb.
3	49	4 yr.; stage 3 (severe)	Shoulders, neck, elbows, wrists, fingers, knees, ankles; 1945, poor response to gold salts	....	250 cc.	4 treatments	12	12 mo.	Grade 2	Flexion deformity of knees corrected; gained 21 lb.
4	48	2 yr.; stage 3 (severe)	Neck, shoulders, wrists, hands, knees, ankles, feet	Asthma, bronchiectasis, 9 yr.	250 cc.	4 treatments	14	6 wk.	Grade 2	Asthmatic attacks infrequent; gained 26 lb.; subcutaneous nodules below both elbows gone after 10 treatments
5	63	18 yr.; stage 3 (severe)	Knees, shoulders, neck, elbows, wrists, hands	....	200 cc.	5 treatments	6	8 wk.	Grade 2	Better than she has been in yrs.; gained 5 lb.
6	52	6 mo.; stage 3 (severe)	Shoulders, elbows, knees, ankles, toes	Psoriasis, 8 yr.	250 cc.	3 treatments	10	18 mo.	Grade 2	Gained 28 lb.; no arthritis, no psoriasis
7	45	10 yr.; stage 3 (severe)	Shoulders, elbows, wrists, ankles, feet; 1945, exfoliative dermatitis 1 yr. after gold salts	....	250 cc.	4 treatments	14	6 mo.	Grade 2	Gained 10 lb.; nodule below elbow disappeared
8	45	3 yr.; stage 3 (severe)	Hands, wrists, elbows, ankles, feet	....	250 cc.	10 treatments	15	16 mo.	Grade 2	Gained 30 lb.

Nephrons and Glomeruli.—Each kidney has about 1,200,000 nephrons, each about 2 inches long, so that the combined length of all nephrons in an adult would amount to 75 miles. The length of individual capillaries in a glomerulus is about one inch: thus, the total of all capillaries in both kidneys would measure more than 37 miles. The entire filtering surface of all glomeruli exceeds twice the body surface.—F. R. Stearns, M.D., Man in Numbers, *Clinical Medicine*, February, 1951.

PROGNOSIS OF ANGINA PECTORIS AND CORONARY OCCLUSION

FOLLOW-UP OF 1,700 CASES

Louis H. Sigler, M.D., Brooklyn

There are comparatively few reports in the literature of large series of cases bearing on the prognosis of angina pectoris and coronary occlusion, and the available reports show considerable differences in their findings. Some of the reports refer only to cases that were followed till death and do not include those of patients still living, thus conveying a wrong impression of the actual prognosis.

As examples of the differences in the longevity figures of angina pectoris as reported in the literature are the following: Herrick and Nuzum [1] in a study of 200 patients, 50 of whom died, found the average longevity for the dead group to be three years. Mackenzie [2] reported on 380 patients, 214 of whom died, with an average longevity for the dead group of 5.4 years. White [3] reported on 200 patients, 66 of whom died with an average longevity of 3.4 years for the dead group. The average longevity of the remaining 134 living patients was 4.6 years. White and Bland [4] reported on 500 patients with angina pectoris who were under observation 23 years, between 1920 and 1943. At the end of that period, 445 were dead, the average longevity being 7.9 years. Of the 52 patients known to be still living, the average longevity was 18.4 years. Eppinger and Levine [5] reported 141 fatal cases, with an average longevity of 4.5 years. In 166 fatal cases of Wedd and Smith [6] the average longevity was 5.8 years. Parker and co-workers [7] reviewed the records of 3,440 cases of the Mayo Clinic. The average survival for their entire group was five years.

Because of the comparatively short time elapsed since coronary thrombosis became a recognizable clinical entity, very few reports have appeared in the literature to date on the ultimate prognosis of this phase of coronary disease. Conner and Holt [8] reported 287 cases, with an immediate mortality of 16.2%.

White [9] reported the case of one man who lived 17½ years and that of another man [10] who lived 25 years after an attack of myocardial infarction. Bedford [11] in a study of 31 cases found the average duration of life to be six months. He remarked that some persons may live more than 5 years. Drake [12] reported on a patient who lived 37 years after an attack of coronary thrombosis. Levine and Rosenbaum,[13] in a study of 372 cases, found the average longevity in 101 fatal cases to be 3.4 years. Master and co-workers [14] found a death rate of 8% up to the time of discharge from acute care in 243 patients with coronary occlusion.

Katz and co-workers [15] reported on 488 patients of myocardial infarction, some of whom were followed for variable periods up to six years. They estimated that about 25% died within the first two months, 50% by the end of the first year and 75% by the end of the third year.

Because of this comparative scarcity of reports on the prognosis of angina pectoris and coronary thrombosis and of the variations in the findings, I considered it of value to review a series of 1,700 cases that came under my observation during a period of 25 years. This report deals with such review.

SELECTION OF CASES

The cases consisted of those of private patients and those seen in consultation. Each case was followed over the entire period of observation either by me or by the physician in charge of the case. Those patients who did not come for a periodic check-up were followed by mail. If no reply was obtained by the time this statistical study was made, the case was not included in this review.

It is realized that the addition of new cases from year to year introduces some error in longevity. Much of this error, however, was partly overcome by a careful history of the exact date of onset of the clinical manifestations of the disease in each case.

COMPOSITION OF CASES

The 1,700 patients whose cases form the basis of this report consisted of 1,302 males and 398 females. The incidence of males to females was thus about 3.2:1. This male-to-female ratio is practically the same as in the report of White and Bland,[4b] but smaller than in that of Parker and co-workers,[7] in which the radio was 4.3:1.

At the time of submission of this report, 1,021 patients were living and 679 were dead. The 1,021 living patients consisted of 814 males and 207 females. The 679 dead consisted of 488 males and 191 females. The total percentage of dead was thus 39.9 for the entire group, 37.5 for the males and 47.9 for the females.

OBSERVATIONS

Mode of Onset of Clinical Manifestations.—The onset of the clinical manifestations in this series is shown in table 1. In 809 cases the anginal syndrome developed and progressed slowly over a period of months or years, while in 891 cases the onset was abrupt in the form of a coronary occlusion with apparently no warning symptoms.

Age at Onset of Clinical Manifestations.—The average age at onset of the clinical manifestations for the entire series of 1,700 cases was 55.8 years. This is a little younger than in the series reported by White and co-workers,[4b] in which the average age at onset was 56.5 years, and still younger than in that of Parker and co-workers,[7] in which the average age was 57.1 years. The youngest ages at onset in our series were 22½ and 20 years, and the oldest were 84 and 93 years respectively, for males and females.

On breaking up the figures of the entire series of 1,700 cases into its male and female, living and dead components and in decades, the following features are observed, as shown in tables 2 and 3.

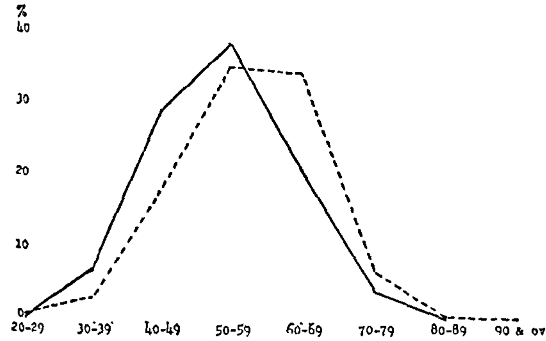

Chart 1.—Age at onset of clinical manifestations of coronary disease in the entire series of 1,700 cases. Solid line, males; broken line, females.

The disease developed in women on the average at an older age than in men and in the dead group at an older age than in the living group. Thus, the average age at onset among women was 56.7 years in the living group and 57.8 in the dead group, while in men it was 51.6 and 54.7 respectively, as shown in table 2. It was also observed that decade by decade the percentage number of cases in which the disease developed after 50 years in men and after 60 years in women is definitely greater in the dead group, as shown in table 3.

In both men and women and in the living and dead groups, the disease developed in the greatest number of patients between 50 and 59 years of age, comprising more than one-third of the cases of the entire series. Second in frequency were the ages 60 to 69 and third in frequency 40 to 49 years. These three age groups together comprised 87.9% of cases in men and 87.2% of cases in women. The rest were distributed in the ages younger than 40 years and older than 69 years. Of this remaining group the males comprised mainly the younger and females the older ages, as shown in table 3 and chart 1.

Age at Death.—The age at death in the group of 679 patients who died varied considerably, as shown in table 5 and chart 2. The average age for males was 58.8 years and for females 61.7 years. The youngest were 23 and 25 years and the oldest 85 and 94 respectively for males and females. A greater percentage of woman than of men lived beyond 60 years of age. The actual figures were 59.2% for females and 50.9% for males. Beyond 70 years of age 17.9% of females and 15% of males were still alive. Beyond 80 years only 3.7% females and 2.3% males were still living.

Table 1.—*Mode of Onset of Clinical Manifestations*

		Slow Onset		Acute Onset	
	Total No.	No.	%	No.	%
Males	1,302	587	45.1	715	54.9
Females	398	222	55.5	176	44.5

Chart 2 illustrates the age at onset and death among males and females per decade in the group that succumbed to the disease.

Length of Survival.—The survival period from the onset of the earliest clinical manifestations of the disease to death varied considerably in different individuals. In the series of 679 patients who died, the average length of survival was 4.7 years for males and 4.5 years for females. The shortest survival was three hours in a man who never presented symptoms of coronary disease and in whom acute coronary occlusion suddenly developed. The longest survival was 35 years in a man in whom signs of the anginal syndrome first developed at 35 years of age and who finally succumbed to an acute attack of coronary occlusion at 70 years.

These survival figures do not depict the true longevity in this disease. To get a true picture we must take into consideration also the length of survival of all living patients. Thus, of the 1,021 patients still alive at the time of this statistical study, the average length of survival was 5.5 years, and for males and females separately 5.3 and 5.6 years respectively. One patient was still living 32 years after the onset of symptoms.

A better idea of survival in this disease is obtained if we divide the entire series of patients into groups of given years, as is shown in table 4.

It will be observed here that in the dead group, 32.8% of the males and 34.5% of the females were still alive at the end of five years. At the end of 10 years 10% of the males and 9.4% of the females were still living. At the end of 15 years the percentages of survivors were 3.5 and 1.6% respectively for males and females. After the 15th year, the survival rate rapidly drops. This is shown graphically in chart 3.

Table 2.—*Youngest, Oldest and Mean Age at Onset of Clinical Manifestations in Years*

	Male		Female	
Age	Living Group	Dead Group	Living Group	Dead Group
Youngest	22½	23½	30	20
Oldest	78	84	87	93
Mean	51.6	54.7	56.7	57.8

In the group of 1,021 living patients the number living up to three years was disregarded, as that period was considered too short to be of value statistically. Those living longer assumed more significance as an index of longevity.

In table 4, under the group of 1,021 living patients, are summarized the number of patients still alive in each given year. It is possible, therefore, to include in any given year all other patients that remained alive longer.

Table 6 shows a few representative years with the number and percentage of patients still alive. It will be observed that as many as 67.1% of the males and 61.4% of the females were alive four years; 54.6% and 46.1% respectively, five years; 15.1% and 15.4% respectively, 10 years and 4.2% and 6.2% respectively 15 years and longer. When compared with the longevity in the dead group the percentage of patients in the living group was far greater year by year. The final longevity will be still greater if these patients are followed over a number of years to come.

It is of interest to find that a relatively smaller number of females than males were alive up to 10 years and a relatively larger number beyond that.

Causes of Death.—Of the 679 patients who died the causes of death were definitely ascertained for 393 cases and summarized in table 7. It will be noted that 83.5% of the patients died of underlying heart disease, the vast majority, namely 67.6% from coronary occlusion. Of the remaining 16.5%, approximately one-third died of cerebral vascular accidents, another third of cancer in various regions of the body, and the rest from a variety of other causes. The longevity in this group with coronary disease would, therefore, have been considerably increased in at least 16% of patients if no intercurrent disease terminated their lives.

Duration Between the Onset of Symptoms of Coronary Disease and First Attack of Coronary Occlusion.—Of the entire series of 1,700 patients, 1,208 had one or more attacks of coronary occlusion during the period of observation, and 492 have not had any attack so far. Of the 1,208 who sustained one or more acute attacks of occlusion, 878 exhibited such an attack as the first manifestation of coronary disease. The other 330 patients have had preexisting symptoms for variable periods before such attack.

In the 330 patients who had shown symptoms previous to the onset of coronary occlusion, the duration between the onset of symptoms and the first attack of occlusion varied considerably, as shown in table 8. The average duration was 3.9 years for male subjects and 3.4 years for female subjects. The longest duration was 21 years and the shortest two hours. *On the basis of these findings* it appears that occlusion occurs most frequently between three months and two years after the onset of the anginal syndrome.

TABLE 3.—*Age at Onset of Clinical Manifestations in Decades*

Duration Between the First Attack of Coronary Occlusion and the Present Age of Living Patients.—Of the 1,208 patients who had at least one attack of coronary occlusion, 785 were still alive when this report was compiled; of these, 650 were males and 135 females. The average duration between the first attack and the present age was 4.9 years for males and 4.5 years for females.

Table 9 summarizes the number and percentage of cases in the respective months and years that elapsed between the first attack of coronary occlusion and the time that this report was compiled.

It will be noted that as many as 45.3% of the males and 37.8% of the females were alive five years or more after the first attack; 10.7 and 10.4 of males and females respectively were still alive 10 years or more, and 2.1% of the males were still alive 15 years or longer.

Duration Between First Attack of Coronary Occlusion and Death.—Of the 423 cases of coronary occlusion who ultimately died, the average duration of life between the first attack of coronary occlusion and death was 3.8 years for males and 3.1 years for females.

TABLE 5.—*Age at Death*

	Males		Females	
Age in Years	No.	%	No.	%
20-29	2	0.4	2	1.1
30-39	11	2.2	3	1.6
40-49	56	11.5	19	9.9
50-59	171	35.0	55	28.2
60-69	175	35.9	78	41.3
70-79	62	12.7	27	14.2
80-89	11	2.3	5	2.6
90 and over	0	....	2	1.1
Mean age	58.8 yr.		61.7 yr.	
Youngest	23 yr.		25 yr.	
Oldest	85 yr.		94 yr.	

TABLE 6.—*Number and Percentage of Patients Alive During the Given Years in the Living Group of 1,021*

	At End of 4 Yr.		At End of 5 Yr.		At End of 10 Yr.		At End of 15 Yr.	
Sex	No.	%	No.	%	No.	%	No.	%
Males	548	67.1	446	54.6	122	15.1	30	4.2
Females	97	61.4	65	46.1	31	15.4	12	6.2

Table 10 summarizes the longevity between the first attack of coronary occlusion and death.

It will be noted that 68.4% of the males and 84.8% of the females died within 4 years after the first attack of coronary occlusion. Only 31.6% of the males and 15.2% of the females lived 5 years of longer, and 8.8% of the males and 7.2% of the females lived 10 years or longer. It is of interest also to find that 1.5% of the males and 1.6% of the females lived 15 years or longer after an acute attack of coronary occlusion.

COMMENT

When we speak of the prognosis of angina pectoris and coronary occlusion, we have in mind the outlook in any given case in which the patient suffers from degenerative coronary disease. The pathology was fully discussed before. In brief, it consists of coronary arteriosclerosis, atheromatosis, and in some cases intra-arterial wall hemorrhages. These changes result in a gradual narrowing and finally complete obstruction of one or more branches of the coronary arterial tree with or without a fresh thrombosis. These degenerative processes usually progress slowly over a period of years and are not detectable until they reach a stage when clinical manifestations appear.

There are many cases in which no clinical manifestations of the disease appear until either an acute episode of coronary occlusion occurs or sudden death takes place. In many of these, autopsy findings may reveal extensive coronary disease which has surely taken years to develop and yet the patient was asymptomatic during life. Thus, in an analysis of the autopsy findings of 2,030 cases of sudden and unexplainable death, Rabson and Helpern[16] found that 45% were attributed to disease of the heart and aorta and 30.4% of these were caused by coronary artery sclerosis. In the latter, 75.5% showed no fresh thrombosis.

TABLE 7.—*Causes of Death in 393 Cases of Coronary Disease*

	Cases

For these reasons the actual prognosis of coronary disease from its early development to death cannot be estimated. We can speak only of the period from the onset of clinical manifestations. When thus considered, we find by experience that in a great many cases the symptomatology of coronary disease, expressed mainly in the anginal syndrome, does not progress uninter-

---

16. Rabson, S. M., and Helpern, M.: Sudden and Unexpected Natural Death, Am. Heart J. 35:635, 1948.

ruptedly from its inception to the end. It exhibits itself by periods of remission or quiescence and exacerbation or crisis. In some cases the anginal syndrome may occur for a variable period and subside, leaving the patient in a comfortable state for many days, weeks, months, or even years, only to recur again. It is very likely, as Blumgart and co-workers[17] have demonstrated, that in many cases during the period when the anginal syndrome is present, closure of vessels is taking place, even though the classic criteria of coronary thrombosis are absent. In many cases of uncomplicated angina pectoris the patients have been found by these authors to have old occlusions of one or more of the coronary arteries. That the typical picture of coronary occlusion was not evident is due to the fact that occlusion was gradual and there was time for a collateral circulation to develop.

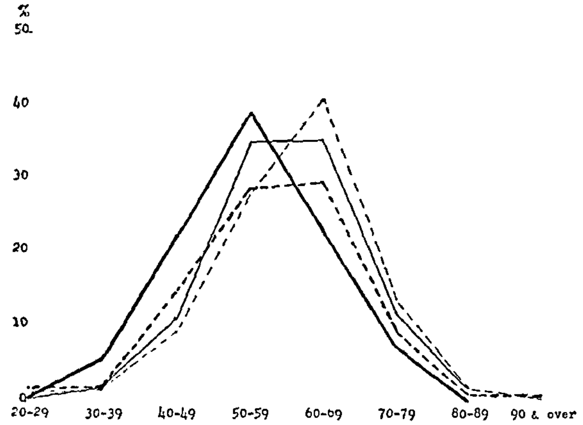

Chart 2.—Age at onset and at death in the group of 679 cases that died from coronary disease. *Solid heavy line, age at onset, males; solid thin line,* age at death, males; broken heavy line, age at onset, females; broken thin line, age at death, females.

Because of the periods of remission of the anginal syndrome, we must be extremely careful in taking a history to determine the exact time of onset of symptoms. In many of the cases of this study it was difficult to fix the exact date of such onset, especially if the syndrome was of long duration. Only on careful inquiry, which was made in each of the cases, and on helping the patient in his recollections by association with other events could the time be fixed. It is therefore, understandable how errors might arise in the study of any series of cases unless great care is exercised. Even then the recollection of some persons may not be entirely reliable.

The mode on onset of the clinical manifestations in our series was either in the form of an acute episode or in a slowly progressing manner. In approximately half of the cases the onset was acute, in the form of the classic manifestations of coronary occlusion. This occurred more frequently in males. It is important to note that even in this acute group, some of the patients gave a history of antecedent vague digestive disturbances and other unexplainable symptoms for a variable period before the acute episode, and these may have been due to coronary insufficiency. For instance, some complained of vague "rheumatic" aches and pains in the shoulders, arms or in the back of the neck appearing at irregular intervals, especially in cold weather, not related to exertion, for some months before an acute attack. Others complained of occasional spontaneous fleeting precordial discomfort, a tired feeling or other vague disturbances.

The observations in this study that in the group who died the disease developed a little later than in the living group would tend to indicate that the chances of survival are greater if the onset of the disease occurs earlier in life. This appears to be contrary to the belief that the earlier the onset of clinical manifestations the shorter the life. This may be true if we compare the longevity of patients with coronary disease with the longevity of the general population, but it does not appear to be true in the longevity curves of patients with coronary disease itself. These findings confirm those of other authors that in women the disease develops later in life and they die later than men. The later death is due not to a greater longevity, but to the later development of the disease.

As pointed out before, in estimating the average length of survival in angina pectoris and coronary occlusion, we must take into consideration not only those patients who died but also those remaining alive over a given period. This is shown in this series, in which the average length of survival in the living group of 1,021 patients at the time of compilation of the statistics was already greater than in the dead group of 679 patients.

The estimated *average duration of life of 4.6 years for the dead group and 5.5 years for the living group in* this series gives an inaccurate idea of the actual longevity. As many as 32.8% of the males and 34.5% of the females were still living at the end of five years in the group of 679 patients who ultimately died. Of the 1,021 living patients as many as 54.6% of the males and 46.1% of the females were alive five years or longer and as many as 15.1% of the males and 15.4% of the females were alive 10 years or longer. The percentage of patients alive 15 years or longer was 4.2 for males and 6.2 for females. One patient was still alive 35 years after the onset of the disease.

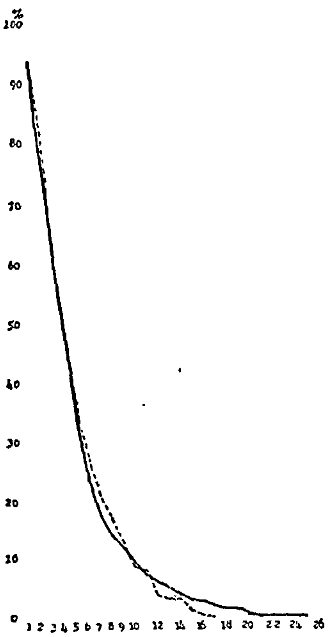

Chart 3.—Percentage of the 679 patients who eventually died still alive at the end of the given year. Solid line, males; broken line, females.

In considering the longevity in coronary disease we must also bear in mind the fact that a good proportion of such patients are killed by other disease. Of the 393 patients for whom the cause of death was ascertainable, 16.5% died from other than the coronary disease. Had life not been terminated by the other diseases, the patient would undoubtedly have lived longer thus lengthening the longevity figures.

17. Blumgart, H. L.; Schlesinger, M. J., and Davis, D.: Studies on the Relation of the Clinical Manifestations of Angina Pectoris, Coronary Thrombosis and Myocardial Infarction, Am. Heart J. **19:** 1, 1940.

The observation in this study that 72.6% of the 1,208 patients with coronary thrombosis had no clinical evidence of coronary disease before the first attack of coronary occlusion is a little higher than that of Conner and Holt.[8] In their series of 287 patients, 62% had no antecedent circulatory symptoms.

13 yr.	3	0.5	0	...
14 yr.	13	2.0	1	0.7
15 yr.	3	0.5	..	...
16 yr. and over	9	1.6	..	...

In 330 patients in the present series who had antecedent symptoms before the first attack of coronary occlusion, the duration of symptoms before the attack varied considerably, the average being 3.9 years for males and 3.4 years for females. However, as many as 27.4 and 32.9% of the males and females respectively had the attack four years or longer after the onset of symptoms and in 6.2% of the males and 5.8% of the females the attack occurred 10 years or longer after the onset. The longest period was 21 years for males and 17 years for females.

Of particular interest in this study is the longevity after the first attack of coronary occlusion. This appears to surpass the findings of Conner and Holt,[8] Katz and co-workers,[15] and of Levine and Rosenbaum.[13] Of 117 patients who recovered from the first attack in the Conner and Holt series, 75% were in good health at the end of the first year, 56% at the end of the second year, 21% at the end of the fifth year and 3.4% at the end of 10 years. One patient lived 18 years and died after a second attack. The comparatively short period of observation and incomplete follow-up in the series reported by Katz and co-workers appears to yield approximately the same findings. Of 101 patients who survived the first attack in Levine and Rosenbaum's series, the average longevity was 41.1 months. About 25% died within one year, 50% within two years and 75% within five years and the remainder between five and 12 years. One was alive 25 years after the first attack.

In the series of 1,208 patients here reported on who have had at least one attack of coronary occlusion, the average duration of life of the 423 who eventually died was only 3.8 years for males and 3.1 years for females. This is approximately the same as in the series of Levine and Rosenbaum.[13] however, of the 785 patients in the series under study who were still alive, the average duration of life up to the time of this report was 4.9 years for males and 4.5 years for females, which greatly surpass the findings of Levine and Rosenbaum, and the patients were all still alive. Likewise, even in the group that ultimately died in the series reported here the specific longevity of the number remaining alive after a given period was considerably longer than in the series of Levine and Rosenbaum and that of Conner and Holt. Thus in the series under study here 83.1% of the males and 81.5% of the females were still alive two years or more after the first attack, and 45.3% of the males and 39.8% of the females were still alive five years or longer. The percentage number still alive 10 years or over was 10.7 for males and 11.4 for females. One of the patients was still alive 30 years after an attack of coronary occlusion. The longevity in this case surpassed that in all the reported cases except that of Drake,[12] whose patient died 38 years after the first attack. There is a possibility that my patient may ultimately reach that longevity, for he was in good health at the time this report was compiled.

SUMMARY

A statistical study was made of 1,700 patients with angina pectoris and coronary occlusion observed over a period of 25 years. Of these, 1,302 were males and 398 females. The ratio of males to females was thus about 3.2:1. Of the entire series, 1,021 were still living and 679 were dead.

The onset of clinical manifestations was slow in 809 cases and abrupt, in the form of an acute coronary occlusion, in 891.

The over-all average age at onset for the entire series was 55.8 years. The youngest age was 20 years and the oldest 93 years. The average age at onset in the living group was 56.7 years for females and 51.6 years for males; in the dead group, 57.8 and 54.7 respectively. The ages at onset in the order of frequency were between 50 and 59 years, 60 and 69 years, and 40 and 49 years. These comprised 87.9% of the males and 87.2% of the females. The balance were distributed in the ages younger than 40 years and older than 69 years, males comprising mainly the younger and females the older ages.

TABLE 10.—*Duration Between First Attack of Coronary Occlusion and Death*

Time	Males (296)		Females (127)

12 yr.	6	2.1	1	0 8
13 yr.	4	1.1	1	0.8
14 yr.	0	...	0	...
15 yr.	1	0.3	2	1.6
16 yr.	1	0.3	..	...
17 yr.	1	0.3	..	...
18 yr.	1	0.3	..	...
30 yr.	1	0.3	..	...

The average age at death for males was 58.8 years and for females 61.7 years. The youngest age was 23 years and the oldest 94 years. The percentage number of patients who lived beyond 60 years of age was 59.2% for women and 50.9% for men; beyond 70 years, 17.9% for females and 15.0% for males, and, beyond 80 years, 3.7 % for females and 2.3% for males.

The average length of survival of the 679 patients who died was 4.7 years for males and 4.5 years for females. The shortest survival was three hours and the longest 35 years. The percentage of patients still living at the end of five years was 32.8 for males and 34.5 for females; at the end of 10 years, 10 for males and 9.4 for females; and, at the end of 15 years, 3.5 for males and 1.6 for females.

The average length of survival of the 1,021 patients that were still living was 5.3 years for males and 5.6 years for females. One patient was still alive 32 years after the onset of symptoms. The percentage of patients still living at the end of 5 years was 54.6 for males and 46.1 for females; at the end of 10 years, 15.1 for males and 15.4 for females, and, at the end of 15 years, 4.2 for males and 6.2 for females.

Of 393 patients the cause of whose death was known, death was due to the underlying heart disease in 83.5% and to other causes in 16.5%.

Of 1,208 patients who had one or more attacks of coronary occlusion, 878 had the attack as a first manifestation of coronary disease. In 330 who had had symptoms previous to occlusion, the average duration from the onset of symptoms to the first attack of coronary occlusion was 3.9 years for males and 3.4 years for females. The longest duration was 21 years and the shortest two hours.

In 785 patients who were still alive after one attack or more of coronary occlusion, the average duration between the first attack and the time when records were reviewed was 4.9 years for males and 4.5 years for females. About 45.3% of the males and 37.8% of the females were alive 5 years or more; 10.7% and 10.4% respectively, 10 years or more, and 2.1%, 15 years or more.

In 423 patients with coronary occlusion who ultimately died, the average longevity after the first attack was 3.8 years for males and 3.1 years for females. About 68.4% of the males and 84.8% of the females died within 4 years after the first attack; about 31.6% of the males and 15.2% of the females lived 5 years or longer; 8.8% of the males and 7.2% of the females, 10 years or longer, and 1.5% of the males and 1.6% of the females, 15 years or longer.

This study, like every other study of this kind, is based on the duration of the clinical manifestations of degenerative coronary disease, not on the duration of the evolution of the structural pathology from its inception. The early phases of the latter, lasting many months or years, are undoubtedly asymptomatic in most cases and, therefore, antecede the clinical manifestations by that length of time. The entire duration of the evolution of structural coronary disease can, therefore, not be ascertained.

THE ACTION OF PROCAINE AMIDE IN CARDIAC ARRHYTHMIAS

Harold Miller, M.D., Morris H. Nathanson, M.D.
and
George C. Griffith, M.D., Los Angeles

It has been demonstrated that procaine applied locally to the heart reduces cardiac irritability as indicated by the added intensity of stimulation necessary to induce extrasystoles or ventricular fibrillation.[1] It has also been shown that after procaine administration a larger dose of epinephrine is required to produce ventricular fibrillation during chloroform anesthesia.[2] Since the administration of procaine in man may be followed by untoward reactions, Burstein and others[3] studied the effect of less toxic substances chemically related to procaine. They found that several related compounds protected dogs from epinephrine-cyclopropane ventricular fibrillation. Brodie, Lief and Poet[4] demonstrated that procaine administered intravenously in man is hydrolyzed rapidly to paraaminobenzoic acid and diethylaminoethanol. Because of the high concentration and relative persistence of diethylaminoethanol in the plasma, Rosenberg and others[5] studied the effect of this compound on cardiac arrhythmias. The drug prevented the development of ventricular ectopic beats in dogs under cyclopropane anesthesia. It suppressed ventricular premature contractions for a variable period in human subjects and restored normal rhythm in six cases of ventricular tachycardia. Its usefulness was somewhat limited by its hypotensive effects and its relatively rapid transformation in vivo. Mark and others,[6] in a search for a drug having the activity of procaine without its toxicity, studied the action of various amides and esters of diethylaminoethanol. They found that the amide of procaine was the most promising in that this compound was not affected by the plasma enzyme that hydrolyzes procaine, plasma levels were well sustained, and the drug could be administered orally, since gastrointestinal absorption was complete. They reported the suppression of ventricular premature contractions in man and the termination of prolonged attacks of ventricular tachycardia in three

out of four patients. Procaine amide differs from procaine only in having the amide grouping (CO.NH.) in place of the ester grouping (CO.O.) of procaine (fig. 1).

SUBJECTS CHOSEN AND METHOD OF STUDY

Our interest was chiefly in the action of procaine amide on rhythms of ventricular origin, since it has been claimed that procaine and diethylaminoethanol affect only such rhythms. However, a group of patients with auricular arrhythmias was also included. In order to eliminate the possibility of spontaneous variations in rhythm, only those patients who had very frequent and persistent premature systoles were selected. Patients who had frequent premature beats alternating with periods of normal rhythm were excluded. In the patients with ectopic tachycardias, the abnormal rhythm had been present for from one to 24 hours before the drug was administered.

TABLE 1.—*Types of Cardiac Disease in Which the Action of Procaine Amide Was Studied*

	No. of Patients
Chronic coronary disease	21
Rheumatic heart disease	9
Hypertension	7
Myocardial infarction	6
Congenital heart disease	1
Syphilitic heart disease	1
No organic heart disease	10

PROCEDURE

The effect of an intravenous injection of procaine amide was studied in 55 patients with various disturbances in cardiac rhythm. (The types of cardiac disease are listed in table 1.) The usual dose was 500 mg.; however, in one patient 250 mg. was used, in two the dose was 400 mg., and in four patients with ventricular tachycardias, a second dose of 500 mg. was administered. At the outset of the study, the drug was administered slowly over a period of two to three minutes. It was found that there were no untoward reactions following a more rapid injection, and in some instances the dose was injected within one minute. However, the rapider injection seemed to have no advantage, and the slower rate appeared to be desirable. A control electrocardiogram was made before the administration of the drug and continued during, and for several minutes after, the injection. Records were then taken at five and 10 minute intervals for a variable period, in some instances for several hours. The pulse was palpated frequently by the observer and a record made whenever a disturbance in rhythm was detected. Frequent blood pressure readings were made and any evidence of untoward effect noted.

TABLE 2.—*Effect of Procaine Amide in 55 Patients*

Type of Arrhythmia	No. of Patients	Result
Premature beats		
Ventricular	31	Ectopic beats eliminated in 26
Auricular	1	No effect
Auricular and ventricular	1	Ectopic beats reduced
Ectopic tachycardias		
Ventricular	8	Cessation of ventricular rhythm in 4, slowing of rate in 4
Supraventricular	4	Sinus rhythm in 3, slowing of rate in 1
Auricular fibrillation with	6	Sinus rhythm in 1, no effect in 5
ventricular premature beats	6	No effect on auricular fibrillation, premature beats eliminated

RESULTS

Of 55 patients who received procaine amide intravenously, the cardiac arrhythmia was modified in 46. Of 31 patients in whom the arrhythmia was due to frequent ventricular systoles, the ectopic beats were eliminated in 26. The effect was observed usually within one minute after the administration of the drug. Frequent auricular extrasystoles were not affected in one patient and in another case beats from auricular and ventricular foci were definitely reduced in frequency. The drug was administered in eight attacks of ventricular tachycardia. The rhythm was unmodified in four, but the rate was definitely reduced. In four instances the ventricular rhythm was abolished. Of four patients who had supraventricular tachycardias, sinus rhythm was restored in three. The drug was administered to 12 patients with auricular fibrillation. The arrhythmia was of the chronic type in 11 and was paroxysmal in one. In the latter patient sinus rhythm appeared within 90 seconds after the injection. It is possible that this effect may have been coincidental and not a result of the drug. However, the appearance of the sinus beats corresponded well with the usual onset of the drug action. In the 11 patients with chronic auricular fibrillation, the auricular rhythm was not modified. Six of these patients also had ventricular premature beats, and these were eliminated in each instance. Although the auricular fibrillation persisted, a slowing and widening of the fibrillation waves was observed. Table 2 shows the effects of the drug in the various arrhythmias. Typical effects of procaine amide are shown in figures 2 to 7.

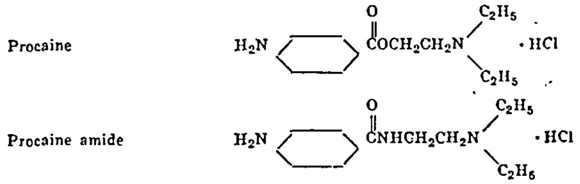

Fig. 1.—Structural formulas of procaine and procaine amide.

COMMENT

The present observations indicate that procaine amide is very effective in abolishing ectopic beats and rhythms. Although our study deals chiefly with ectopic ventricular rhythms, there is evidence that supraventricular rhythms may also be influenced. In therapeutic doses, there are either mild untoward reactions or none. The mechanism of action of the drug requires further study. The fact that ventricular beats are more consistently affected suggests that the drug does not produce its effect entirely by a quinidine-like action. Quinidine sulfate inhibits both auricular and ventricular rhythms, and its action on the refractory period can be clearly demonstrated on the auricle of the experimental animal. The predominant

distribution of the sympathetic innervation is on ventricular rhythmic foci,[7] which suggests that procaine amide may exert its effect by a sympathetic blocking action. It has been demonstrated that the related compound diethylaminoethanol has potent sympatholytic action.[8]

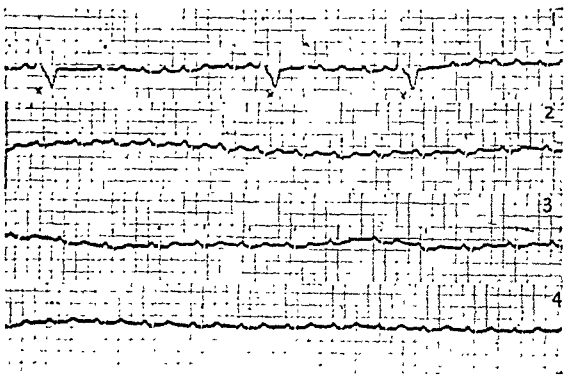

Fig. 2.—Electrocardiogram of patient M. S., a woman 45 years of age, who had frequent and persistent extrasystoles and one or two attacks of paroxysmal tachycardia daily for six months. During this period she was never free of consciousness of the heart beat for more than 3 or 4 seconds. After 400 mg. of procaine amide by vein, there was abolition of the premature beats with complete disappearance of the subjective sensations in the chest. Strip one shows the ventricular extrasystoles, strip 2, 3 and 4 taken two, ten and thirty minutes after the injection of the drug. The arrhythmia was almost completely controlled by the oral administration of 500 mg. three times a day.

Our reliance on the therapy of ventricular ectopic beats and rhythms has been almost entirely limited to the use of quinidine. Although this drug has been a great addition to cardiac therapeutics, it may at times fail to act. In two patients who were relieved of a ventricular tachycardia by procaine amide, previous administration of quinidine in adequate dosage had been ineffective. In emergencies such as prolonged exhausting attacks of ventricular tachycardia, the administration of quinidine by vein has been followed by severe reactions and an occasional fatal outcome. Procaine has been used effectively by vein in the therapy of ectopic ventricular rhythms. Although precautions in the mode of administration have reduced unfavorable reactions, unpredictable toxic effects may occur. Rovenstine and Popper[9] state "that effective intravenous procaine medication can be had by an amount of the drug that continuously provides mild toxic manifestations." They point out that more serious reactions may occur. Reactions to intravenous procaine amide were mild and infrequent. Occasionally, the patient complained of a bitter taste during the injection, and at times there was a flushing of the face. A moderate hypotensive effect was observed in some patients. In two patients with ventricular tachycardias a more marked drop in blood pressure was noted. It is possible that this reaction can be avoided by a slow injection of the drug. At the onset of our studies, the drug was injected at a slow rate. Since no untoward reactions were observed, the speed of administration was gradually increased. This rapider injection appeared to be well tolerated. Kayden[10] feels that the possibility of reactions may be reduced by a slower administration and suggests that the drug be injected at a rate of 200 mg. a minute. Since we have seen no definite advantage in a rapider rate, it would seem that the slower injection may be desirable. No hypotensive effects were observed after oral administration. Occasionally, mild to moderate gastric discomfort was noted, and three patients complained of a sense of "tension and jitteriness" while on maintenance doses of procaine amide by mouth.

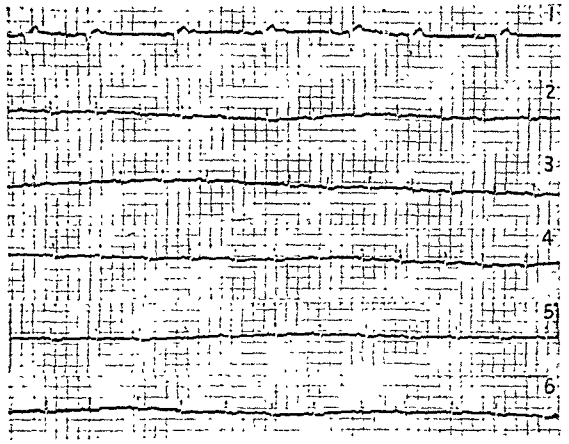

Fig. 3.—Electrocardiogram of patient S. S. Strip 1 shows a bigeminal rhythm, which was due to overdigitalization. Strips 2, 3, 4, 5 and 6 taken during, and five, ten, twenty and thirty minutes after, the intravenous administration of 500 mg. of procaine amide. Oral administration of 500 mg. of the drug every four hours controlled the arrhythmia.

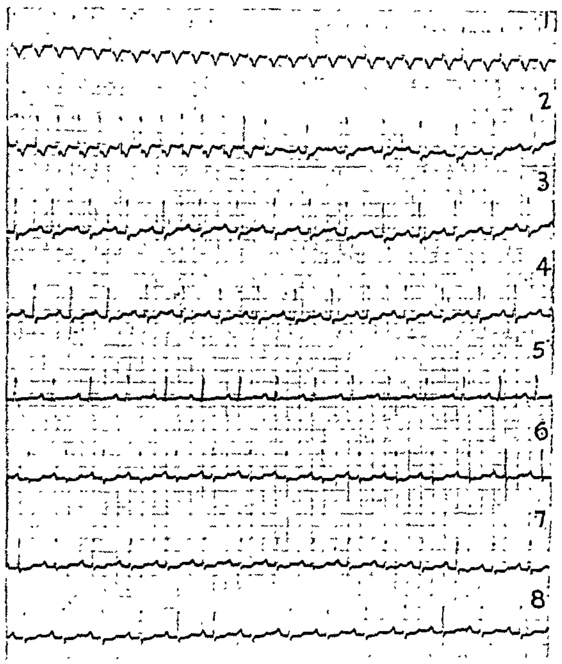

Fig. 4.—Electrocardiogram of patient F. Y. Strip 1 shows a supraventricular tachycardia, rate 184. Strip 2, taken during the intravenous injection of 500 mg. of procaine amide, shows the restoration of sinus rhythm. Lower strips taken one, five, ten, fifteen, twenty and sixty minutes after the administration of the drug.

Further experience may modify the clinical applications and the optimum dosage of the drug. For the present, it would appear that the drug is indicated in the therapy and prevention of ectopic beats and ectopic tachycardias. This includes the application of the drug in the prevention and therapy of arrhythmias occurring

during anesthesia, especially in patients who require thoracic surgery. It would seem justifiable to use the drug routinely after a coronary thrombosis, in order to prevent serious arrthythmias, including ventricular fibrillation. It is now known that varying degrees of ventricular acceleration and ventricular fibrillation may be the basis of the Adams-Stokes attacks in heart block. No effective drug has been suggested for such attacks, but procaine amide appears to be indicated. The effectiveness of the drug in these situations must be determined by further observation.

As to the mode of administration and dosage, it appears that most arrhythmias can be controlled by the oral administration of the drug. For patients with prolonged attacks of ventricular tachycardia, it may be advisable to administer the drug by vein. Orally, the dose varies from 0.5 Gm. three times a day to 1.0 Gm. every three or four hours. Intravenously, a dose of 0.5 Gm. may be injected slowly and the response noted by observation of the heart rate or, preferably, by the electrocardiogram. If the ectopic rhythm persists or the heart rate is not effectively reduced, an additional 0.5 Gm. may be injected. Blood pressures should be recorded and the injection discontinued if a marked hypotensive reaction occurs. It should be pointed out that a definite reduction of the ventricular rate to 110 to 120, without restoration of sinus rhythm, may in some instances be considered a satisfactory response. The slower rate, although still idioventricular in origin, lessens the danger of cardiac or circulatory failure.

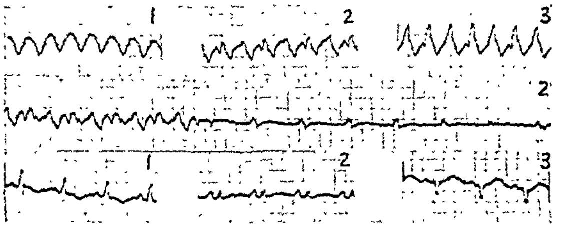

Fig. 5.—Electrocardiogram of patient L. M. Upper strips are leads 1, 2 and 3 showing a ventricular tachycardia, rate 160. This record was taken when the attack had been present for 18 hours, during which time the patient had received 400 mg. of quinidine sulfate orally every two hours. The middle strip shows the cessation of the ventricular rhythm, one minute and fifteen seconds after an intravenous injection of 500 mg. of procaine amide. The auricular waves are absent at this time but appear in the record taken an hour later, the lower strips.

The duration of the effect of an intravenous administration of the drug was variable. In some patients occasional premature systoles appeared within six or seven minutes. In other instances the extrasystoles were absent after two hours of observation. It is probable that the duration of the normal rhythm is not related to the duration of the actual pharmacological action of the drug. Premature systoles and ectopic tachycardias have been ascribed to several mechanisms, and under different circumstances several factors may be operative. Clinical experience in the therapy of cardiac arrhythmias indicates that a drug may alter the abnormal mechanisms causing an arrhythmia and that the restored normal cycle of events in the heart persists after the drug action has subsided. It is not the rule for a therapeutically terminated ectopic tachycardia to recur when the effective mechanism has ceased to act. As illustrations, carotid sinus pressure or the injection of methacholine (mecholyl®) for supraventricular tachycardias have a brief physiological action, but if sinus rhythm is induced, it usually persists.

SUMMARY

Procaine amide was administered intravenously to 55 patients with various cardiac arrhythmias.

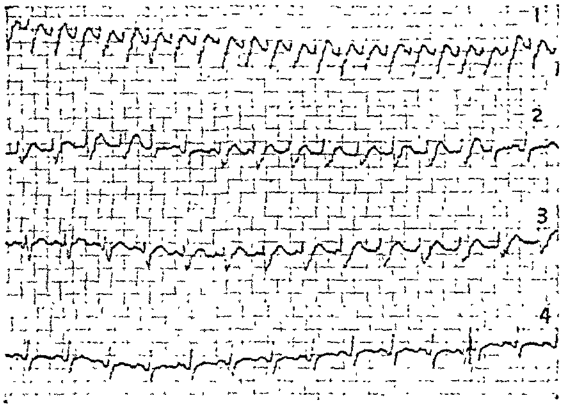

Fig. 6.—Electrocardiogram of patient A. S. Strip 1 shows a ventricular tachycardia, rate 164. Strip 2, taken after an intravenous injection of procaine amide, 500 mg., shows a rate of 114. Strip 3, taken after 800 mg. of procaine amide was administered, shows a rate of 100. Strip 4, taken after 1 Gm. of procaine amide shows sinus rhythm, rate 94.

Ectopic ventricular beats were usually abolished within one minute after the drug was injected.

Sinus rhythm was restored in three out of four attacks of supraventricular tachycardia.

Of eight attacks of ventricular tachycardia, normal rhythm was restored in four, and in four instances the ventricular rate was effectively reduced.

Sinus rhythm was restored in one instance of paroxysmal auricular fibrillation. In 11 patients with chronic auricular fibrillation, normal rhythm was not established. In six patients with auricular fibrillation and frequent ventricular extrasystoles, the ectopic beats were abolished and the auricular rhythm unaffected.

It was demonstrated that arrhythmias could be controlled by oral administration of the drug.

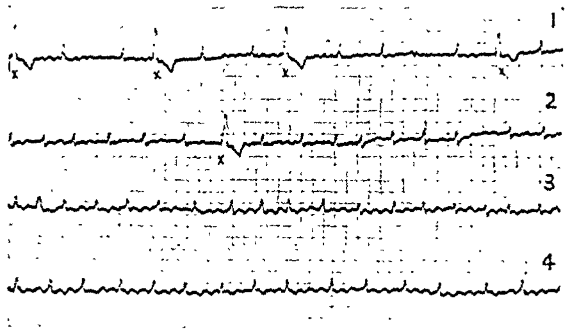

Fig. 7.—Electrocardiogram of patient D. A. Strip 1 shows auricular fibrillation and frequent ventricular extrasystoles. Strip 2, taken immediately after the intravenous injection of 500 mg. of procaine amide, shows only one extrasystole. Extrasystoles are absent in strips 3 and 4, which were taken five and ten minutes later, and were absent during an observation of one hour. The auricular fibrillation is seen to have persisted, but there is a slowing and widening of the fibrillation waves (strips 3 and 4).

The drug was well tolerated, and untoward reactions were infrequent and of a mild nature.

DIGITALIS IN ACUTE MYOCARDIAL INFARCTION

John Martin Askey, M.D., Los Angeles

This study is concerned with the question: Does digitalis in therapeutic amounts increase the incidence of ectopic rhythms in the presence of myocardial infarction? The lack of a convincing answer is responsible for an unusual therapeutic paradox. Largely because of fear of induction of dangerous ectopic ventricular rhythms, digitalis, the most efficacious drug known for congestive heart failure, is given hesitantly for the congestive heart failure associated with myocardial infarction. The evidence that therapeutic doses of digitalis cause ventricular ectopic arrhythmias in the human with myocardial infarction is not convincing. The data presented largely comprise sporadic instances of arrhythmias associated with the use of the drug, which can be ascribed as logically to the coincidental use as to the effect of the drug. Clinical observations have been usually without an adequate control series.

Opinions as to the proper use of digitalis in myocardial infarction vary almost with the individual. One can find good authority for fearing digitalis or for not fearing it; for using it for early congestive failure or for using it only if the failure is progressive; for avoiding digitalis in certain stages or for using it at any stage; for giving small doses because of a supposed diminished tolerance or for giving digitalis in large doses intravenously because such patients respond only to large doses.[1] A recent report by Gilson and Schemm [2] of four cases in which paroxysmal ventricular tachycardia occurring in association with myocardial infarction disappeared after the administration of digitalis indicates the need for reexamining the role of the drug.

This paper is a study of the arrhythmogenic effect of a therapeutic dose of digitalis as determined in two groups of patients with proved myocardial infarction. They were similarly treated save for one variable: One group received digitalis.

MATERIAL

Over a period of several years alternate patients with myocardial infarction, proved by typical electrocardiographic patterns, have been given digitalis. This is a study of the first 100 patients.

To make the study more definitive, patients with serious complications were excluded. It was felt that an arrhythmogenic effect of digitalis upon an area of myocardial necrosis could be evaluated better in the absence of complications than in their presence. Patients moribund, in severe shock, or in obvious congestive failure on admission were excluded. Patients who had been receiving digitalis or quinidine prior to the attack were excluded. Those with any history of an arrhythmia prior to the infarct were excluded. If an arrhythmia was present at the onset, the patient was arbitrarily considered to have had the arrhythmia before the myocardial infarction, since in most instances it could not be proved otherwise. The group studied, therefore, comprised patients with proved myocardial infarction who were not apparently in any immediately critical condition. In all instances administration of the drug was started in the first week after the attack. Digitoxin was given in 0.2 mg. doses three times daily for two days and then 0.2 mg. once daily for the remainder of the hospital stay. Since the average stay was more than three weeks, the patients received digitoxin for more than two weeks. Digitoxin was given slowly because of studies indicating a lower requirement in myocardial infarction.[3] The first 16 patients were treated without bishydroxycoumarin, of whom 8 received digitalis; the remaining 84 patients received the drug during the hospital stay.

The period of study was the period of the hospital stay, or slightly less than four weeks. The objective criteria for evaluating the effect of digitalis, as defined at the outset of the study, were the number of deaths, the number of sudden deaths, and the frequency of disturbances of rate and rhythm. The heart of each patient was auscultated several times daily. Any disturbance in rate or rhythm was checked by electrocardiogram. It is important to know the length of time the heart is examined when one is evaluating the incidence of premature beats. In most cases it was a rule to listen for two minutes. Although admissible that occasional premature beats may have been missed owing to the small fraction of the 24 hr. covered, any error should apply equally to the two groups.

UNDERLYING HEART DISEASE

The two groups seemed to be comparable so far as the degree of underlying heart damage was concerned. The groups were analyzed as to age, sex, previous hypertensive cardiovascular disease, history of anginal pain prior to a month before the attack, or history of previous cardiac infarction. The ages ranged in one group from 45 to 85, and in the other from 39 to 82. The average age was 60.2 years in one group and exactly 60 in the other. The incidence of previous cardiovascular disease as evaluated from the history and examination was essentially the same in each group. A history of previous hypertensive cardiovascular disease, of anginal symptoms, or of previous episodes of cardiac infarction was obtained in 32 per cent of one group and in 34 per cent of the other. Despite the small number in each group, the distributions of these findings were remarkably similar (table 1).

If one allows for the instances in which two conditions occurred in the same patient, there were 62 patients of the 100 in whom there had been previous infarction, previous hypertension, or previous angina. Our criteria for hypertension were blood pressure values over 150/90 on examination or a definite history of preexisting hypertension. The incidence of hypertension is lower than the percentage in an unselected group [4] (36 to 46 per cent), as would be expected.

EARLY CONGESTIVE FAILURE

Although obvious congestive failure was not present in any patient, findings suggesting early congestive failure were equally distributed in the two groups. The data necessary to make such a diagnosis in the presence of myocardial infarction are controversial. If a prolonged circulation time (more than 16 sec. from arm to tongue) is accepted as evidence of early left ventricular failure, the majority were in early congestive failure. Basal râles in the lungs were mentioned in about half of the patients in each of our groups studied. These findings are in accord with those of Selzer,[5] who found that patients with acute myocardial infarction had both a prolongation of the circulation time and a concomitant reduction in the vital capacity.

There is other evidence that pulmonary congestion occurs in most instances of myocardial infarction. Massie and Miller [6] examined the chests of 16 patients with myocardial infarction by X ray within 24 hr. of the acute attack. There was roentgenologic evidence of pulmonary congestion in 12 of the 16 patients, but only 7 of the patients had basal lung râles. Absence of lung râles does not rule out pulmonary congestion.

CIRCULATION TIME

Arm-to-tongue circulation times were determined with dehydrocholic acid (decholin®) on 54 patients during the first week. In only 10 of the 54 were times under 16 sec. recorded. In the majority they ranged between 20 and 30 sec. In 31 patients a second determination was made after one week. A group of 17 patients who were given digitalis at the onset of the attack had an average circulation time of 25 sec. at the onset. One week later the circulation time was 18 sec. A group of 14 patients who received no digitalis had an average circulation time of 22 sec. at the onset and 17 sec. after one week.

RESULTS

The results for the two groups are remarkably similar (table 2). The low mortality rate, 8 per cent (in a private hospital where the over-all mortality rate is around 20 per cent), is a reflection of a selected group, free from complications. The slight difference in the number of deaths and in the incidence of sudden death is probably insignificant. Among the first 16 patients who received no bishydroxycoumarin, there was one death in the group that received digitalis and one death in the group that received no digitalis.

The incidence of auricular fibrillation and of auriculoventricular conduction defects is within the expected range. A number of arrhythmias were present at the onset of the attack and were excluded. Two patients on admission had complete auriculoventricular heart block, two had auricular fibrillation, and seven had ventricular premature beats. The elimination of those patients who showed premature beats at the onset of the attack probably removed from the study a large percentage of those in whom ectopic contractions would develop from the effect of the cardiac infarction alone. Experimentally, ectopic beats develop immediately or within eight hours in animals whose coronary arteries are ligated.[7] It is probable that the above excluded arrhythmias present at the onset resulted from the myocardial infarction, but it could not be proved that they were not present before. The preponderance of the ventricular ectopic beats in the group receiving no digitalis was surprising. There were four instances of ventricular premature beats; in two instances there occurred runs of three or more ectopic beats, the initial stage of ventricular paroxysmal tachycardia. Normal sinus rhythm returned in both instances after a few injections of quinidine, and both patients survived. In the single patient in whom ventricular premature beats developed among the 50 who received digitalis, occasional ectopic beats occurred after three weeks just prior to discharge from the hospital.

however, an attempt at a carefully controlled clinical study. Certain significant facts developed from the study.

Fifty patients with proved myocardial infarction were given digitalis in effective doses without development of any dangerous ventricular rhythms. These results are contrary to what was expected, based on the experimental work on animals and the opinions of clinicians. If digitalis increases the excitability of the necrotic myocardial focus, it theoretically should have increased the incidence of ectopic ventricular rhythms. In this study the group that received digitalis actually had fewer ventricular premature beats. It cannot be deduced from the small series that this difference is significant. The results, however, emphasize the need for the reexamination of the role of digitalis in the presence of myocardial infarction.

The evolution of the fear of digitalis in myocardial infarction has been gradual. In Herrick's [8] original classic paper of 1912, he advocated the routine use of digitalis. Hamman [9] in 1926 said: "The patient should be promptly and fully digitalized. . . .Not only is the digitalized heart better prepared to withstand the added burden of certain arrhythmias should they come on, but it is also stimulated to put forth its best efforts. How desirable the best efforts may be when a large area of heart muscle is infarcted, needs no further comment." Gradually reports of ventricular paroxysmal tachycardia resulting from excessive amounts of digitalis appeared. Since both myocardial infarction and digitalis in toxic doses were capable of inducing the hazardous arrhythmia, digitalis in smaller dosage was assumed to have an additive effect if given in the presence of cardiac infarction. Experimental work done on animals [3] following ligation of coronary vessels showed that only three-fourths as much digitalis was required to cause a ventricular ectopic rhythm and death as in the normal animal. Other work indicated a lessened tolerance of the heart to digitalis after experimental infarction.[3b] The resultant caution advised in the use of digitalis was interpreted by many as a reasonable indication for using the drug only for desperate situations. As Levine [10] expressed it, "It is this very vulnerability of the heart to digitalis in coronary artery disease and coronary thrombosis that, among other conditions, has militated against its use in those conditions." These animal studies, however, are only evidence of a lower lethal dose of digitalis in the presence of myocardial infarction. There has been no study made of the effect of varying doses of digitalis upon the incidence of ventricular premature beats which occur following ligation of a main coronary artery in animals.

The precise place for the use of digitalis needs further elucidation. It is questionable if the results derived from experiments on animals with normal arteries and hearts and under abnormal conditions can be applied to man without more critical appraisal. It is questionable if animal experiments can answer adequately the questions and solve the problems that confront the clinicians. The ultimately significant data must be logically obtained from observation of the effect of digitalis on man who has suffered a spontaneous myocardial infarction. Such data must be of sufficient amount to permit statistical analysis. The role of digitalis could best be determined by some mass study such as led to the rapid elucidation of the role of bishydroxycoumarin in the treatment of myocardial infarction. Such studies are the joint responsibility of many qualified institutions.

Until such studies are completed, I feel justified in using digitalis more freely in the presence of myocardial infarction. Instead of following the common advice to use digitalis only if congestive failure is progressive, or to withhold it until unmistakable signs of both right and left ventricular failure are present, it would seem wiser to administer the drug for the early signs and symptoms. Basal lung râles probably should not be regarded as transitory unimportant findings, but should be routinely supported by other data such as determination of the circulation time and of the vital capacity. If early left ventricular failure is suspected to be present, there is no evidence in this study to support a policy of withholding digitalis until signs of marked failure appear.

The recent report of Schemm [11] would indicate that the profession has been failing to take full advantage of a valuable drug. Thoreau said, "It is never too late to give up our prejudices. No way of thinking, however ancient, can be trusted without proof."

SUMMARY

In a group of 50 patients with proved myocardial infarction and no obvious complications, the administration of digitalis in therapeutic amounts, started in the first week and continuing throughout the hospital stay, induced no more ventricular ectopic rhythms or instances of sudden death than occurred in a control group of 50 treated without digitalis.

Without further evidence the fear of catastrophic arrhythmias should not be cited as a deterrent to the use of average doses of digitalis for the early signs and symptoms of congestive heart failure in myocardial infarction.

Striving Toward Better Methods.—Prof. John Dewey's definition of a good man is a man who is constantly getting better. This is particularly applicable to the definition of a good doctor, namely, one who is constantly getting better. Medicine itself is improving by the day, and woe betide the doctor who stands still, because medicine is moving so fast that he is soon left behind. You have got to keep swimming or you will sink. The great trouble with the devotees of cults in the healing art is that they profess to have found the true and only way to heal the sick. They are shackled by their creeds, and stagnate in fundamentalist doctrines. Whereas regular medicine, dissatisfied with its limitations, is constantly striving toward better methods of preventing sickness and healing the sick.—Conrad Wesselhoeft, M.D., Some Remarks on the Privilege of Practicing Medicine, *The Diplomate*, February 1951.

RS-T SEGMENT, T WAVE AND HEART RATE AFTER TWO STEP AND 10 PER CENT ANOXEMIA TESTS

Sidney Storch, M.D.
and
Arthur M. Master, M.D., New York

The Master "two step" test and the anoxemia test of Levy are accepted as useful objective tests in the diagnosis of coronary artery disease.[1] These tests are particularly valuable in those cases in which coronary artery disease is suspected, but clinical examination and resting electrocardiogram are negative. In both procedures, the first by means of standardized exercise, the second by inhalation of a 10 per cent oxygen mixture, relative anoxemia of the myocardium is produced, which in persons with heart disease will be most frequently revealed by certain abnormal electrocardiographic findings—each test having its own criteria for an abnormal response.

Since abnormal electrocardiographic changes may occur in normal persons subjected to excessive exercise,[2] and negative tracings may result in persons with coronary disease if the exercise is insufficient, the exercise employed in the two step test has been standardized for age, weight and sex. The criteria for an abnormal electrocardiographic response in this test are:

1. Depression of the RS-T segment below the isoelectric level (P-R level) of more than 0.5 mm. in leads 1, 2 or 4.
2. Change from an upright T wave to an isoelectric or inverted T wave (or change in T wave in the opposite direction).
3. Presence of arrhythmia immediately after exercise, which was not present before exercise, and which reverts to normal, e. g., A-V block.

The Levy anoxemia test is based on the inhalation of a mixture of 10 per cent oxygen and 90 per cent nitrogen that is passed through water. Flutter valves are incorporated in the apparatus, so that rebreathing is avoided. A tank of 100 per cent oxygen is incorporated in the circuit, so that oxygen can be administered quickly if needed. Levy's criteria for a positive test are:

1. The sum of the RS-T deviations in leads 1, 2, 3 and 4 F should be greater by 3 mm. or more than in the control tracing.
2. Partial or complete reversal of the direction of the T wave in lead 1, accompanied by RS-T deviation of 1 mm. or more in this lead.
3. Complete reversal of the direction of the T wave in lead 4 F regardless of any associated RS-T deviations in this lead.

In the routine two step test resting control electrocardiographic tracings are taken with limb leads and all chest leads from 1 to 6. Tracings using the three limb leads and the chest V_4 position are recorded immediately after exercise and again at the end of two minute and six minute intervals. If these tracings do not return to normal limits, another electrocardiogram is made at the end of 10 minutes.

In the routine anoxemia test a resting electrocardiogram is made as a control. Tracings are taken at five minute intervals during inhalation of the 10 per cent oxygen-nitrogen mixture, then one minute after inhalation of 100 per cent oxygen and again five minutes after breathing room air.

METHOD

For this study the Master two step test and the Levy anoxemia test were carried out on 23 patients who had normal resting electrocardiograms but histories of precordial pain of varying degrees of severity. To permit detailed comparison of the results of the two tests, tracings were taken at one minute intervals for 10 minutes after exercise and at one minute intervals for 20 minutes during the anoxemia test. Our purpose was to compare heart rate, RS-T segments and T waves at various time intervals and to determine whether or not changes, if occurring during the 10 per cent anoxemia test, corresponded at any time interval to changes observed following the two step exercise test. Since in both tests the criteria are based chiefly on RS-T deviations and T wave changes, changes in the P wave and Q, R and S deflections were not considered of importance for this study. In all cases the tests were given on different days but within a day or two of each other and under as nearly similar conditions as could be obtained. In the two step test use of the Sanborn cardiette® made it possible to complete the electrocardiogram within 30 to 40 seconds after exercise. All records before and after exertion were made with the patient recumbent in bed. The isoelectric reference point for RS-T deviations was the P-R level, and the depression of the RS-T segment was measured from this base.

Table 1 shows the incidence of sex and age distribution in the series of 23 patients. All these patients were ambulatory.

In table 2 a comparison of the heart rate immediately following the two step exercise test and the heart rate at the end of the longest period of inhalation of 10 per cent oxygen in the anoxemia test is given. The latter period was 20 minutes except in those cases in which the test

had to be stopped. In table 2 will also be found the most rapid heart rate observed during the tests in each case and also the positive and negative responses. The results are correlated with age, sex and previous clinical diagnosis. The most rapid heart rate in the two step exercise test was present in the electrocardiogram taken immediately after exertion except in two cases. In these the heart rate was most rapid at the end of one minute after exercise; thereafter it dropped quickly to the resting level. In the anoxemia test no correlation was found between the period of anoxemia and the heart rate. The heart rate generally increased with the duration of anoxemia but not as much as it did in the two step exercise test. Furthermore, in some patients the heart rate fluctuated considerably during the entire period of anoxemia. The heart rate was most rapid during the first 10 minutes in 17 of the 23 patients. In 10 instances the heart rate was highest during the first five minutes. Not at any time was there correlation between the heart rate during periods of anoxemia and the heart rate after exercise. This was true when the results of the two tests were the same and also when they differed. It should be noted however that four of the negative anoxemia tests were stopped before the full 20 minute period of anoxemia, two were discontinued at 18 minutes, one at 12 minutes and one at eight minutes. Three of the positive anoxemia tests were stopped at 11, five and three minutes respectively. Even in these seven tests that were suspended before the full 20 minutes had elapsed the most rapid heart rate was present at the longest period of anoxemia in but two instances, one a negative and one a positive test.

TABLE 1.—*Age and Sex Distribution*

		Sex	
Age, Yr.	No. of Cases	Male	Female
21-30	2	1	1
31-40	1	1	0
41-50	5	3	2
51-60	9	7	2
61-70	6	6	0
Totals	23	18	5

In table 3 is a comparison of the maximum RS-T segment depression in each lead with the time interval at which this depression appeared during the test. It is important to note that the depression of the RS-T segment was measured from the isoelectric base line (P-R level). In the exercise test RS-T segment depressions appeared most frequently in lead 2, then in leads 1, 3 and 4 in that order. The deepest RS-T segment depressions, however, appeared in lead 4, then in leads 2, 1 and 3 in that order.

In the anoxemia test no correlation was present between the degree of RS-T segment depression and the period of anoxemia, nor could any correlation be made between the period of anoxemia and the time interval following the two step exercise test with regard to RS-T segment depression. The anoxemia test thus differed from the two step exercise test, in which 95 per cent of the maximum RS-T segment depressions appeared in the tracing made immediately after exercise.

The maximum RS-T depression, like the maximum heart rate, when present in the two step test, occurs in the tracing recorded immediately after exercise in the great majority of patients. Analyzing each of the standard limb leads and the chest 4 position, the following is found:

Lead 1: All the maximum RS-T depressions occurred in the tracing taken immediately following exercise.

Lead 2: All the maximum RS-T depressions occurred in the tracing immediately after exercise.

Lead 3: In case 10, a negative test, the greatest RS-T segment depression occurred in the five minute tracing. In the others the greatest RS-T depression was in the immediate recording.

Lead 4: In case 20 the greatest depression occurred in the two minute tracing. In the others the maximum RS-T depressions occurred in the immediate tracing.

In the tracings taken immediately after exercise when RS-T segment depressions of over 0.5 mm. occurred they were present in lead 1 in 89 per cent of the cases, in lead 2 in 100 per cent, in lead 3 in 71 per cent and in lead 4 in 71 per cent. However, the lead that showed the deepest RS-T segment depressions was lead 4, then leads 2, 1 and 3 in that order.

Analysis of depression of the RS-T segment in the anoxemia test shows the following results:

Lead 1: In three positive cases the maximum RS-T segment depressions occurred at 20 minutes (case 13); two minutes (case 14), and at two minutes (case 15).

Lead 2: In five positive anoxemia tests the maximum RS-T segment depressions appeared at 20 minutes (case 13); four minutes (case 14); two minutes (case 15); 11 minutes (case 16), and at 10 minutes of anoxemia (case 17).

Lead 3: In two positive cases the maximum RS-T depressions appeared at two minutes (case 14), and at 15 minutes (case 16).

Lead 4: In three positive cases the greatest RS-T segment depressions appeared at 20 minutes (case 13); three minutes (case 15), and at nine minutes (case 17).

Again it is to be noted that even in those cases where the test was discontinued the maximum RS-T segment depressions were not always present at the longest period of anoxemia.

Table 4 shows in each lead the height of the T wave in the immediate tracing of the exercise test and at the longest period of anoxemia in the anoxemia test (which was at the 20 minute period unless the test had to be suspended).

Analysis of the table shows that, as has been generally thought, the T wave is reduced in height after exercise or anoxemia.[3] However, this reduction did not occur in all cases in this study. In fact, the T wave in lead 3 became taller in 52 per cent of the cases in the tracing immediately after exercise. In addition, in lead 4 the number of cases that showed heightening of the T wave and lowering of the T wave was the same.

In the two step test the T wave in the tracing made immediately after exercise changed as follows:

Lead 1: In 52.2 per cent of the cases the T wave became smaller; in 13 per cent of the cases it became taller, and in 34.8 per cent it remained unchanged.

---

[3] (*a*) Baum, W. S.; Malmo, R. B., and Sievers, R. F.: A Comparative Study of the Effects of Exercise and Anoxia upon the Human Electrocardiogram, J. Aviation Med. **16**: 422, 1945. (*b*) Biörck, G.: Anoxemia and Exercise Tests in the Diagnosis of Coronary Disease, Am. Heart J. **32**: 689, 1946.

Lead 2: In 52.2 per cent of the cases the T wave became smaller; in 17.4 per cent of the cases it became taller, and in 30.4 per cent it remained unchanged.

Lead 3: In 17.4 per cent of the cases the T wave became smaller; in 52.2 per cent of the cases it became taller, and in 30.4 per cent it remained unchanged.

Lead 4: In 39.1 per cent of the cases the T wave became smaller; in 39.1 per cent of the cases it became taller, and in 21.8 per cent of the cases it remained unchanged.

In none of the 23 cases was a positive exercise test based solely on T wave changes. In those cases in which abnormal T wave responses did occur there were also abnormal RS-T segment alterations (cases 13, 14 and 15).

* The time given for the highest heart rate in the anoxemia test is the time of such rate's first appearance.

† In case 9 the anoxemia test was stopped at 12 minutes, in case 12 at 18 minutes, in case 14 at five minutes, in case 15 at three minutes, in case 17 at 11 minutes, in case 18 at eight minutes and in case 19 at 18 minutes. In all other cases the full 20 minute period of anoxemia was completed.

In the anoxemia test the T wave was altered as follows at the 20 minute or other greatest period of anoxemia (in those cases in which the test was discontinued before the full 20 minute period of anoxemia was reached the height of the T wave at the minute at which the test was stopped was used):

Lead 1: In 60.9 per cent of the cases the T wave became smaller; in 8.7 per cent of the cases it became taller, and in 30.4 per cent it remained unchanged.

Lead 2: In 47.8 per cent of the cases the T wave became smaller; in none of the cases did it become taller, and in 52.2 per cent it remained unchanged.

Lead 3: In 39.1 per cent of the cases the T wave became smaller; in 17.4 per cent of the cases it became taller, and in 43.5 per cent it remained unchanged.

Lead 4: In 47.8 per cent of the cases the T wave became smaller; in 8.7 per cent of the cases it became taller, and in 43.5 per cent of the cases it remained unchanged.

In one case there was complete reversal in the direction of the T wave in lead 4 F, i. e., an inversion, and this occurred at the 19 minute period of anoxemia; the T wave measured –0.5 mm. After one minute of 100 per cent oxygen the T wave became upright to a height of 1 mm. and remained upright. This was the only one of the positive anoxemia cases that was based on the criterion of T wave inversion in lead 4 alone.

No untoward reactions were encountered in any of our patients during the two step exercise test, and each of the 23 two step tests were completed. During the anoxemia test, however, a shocklike state appeared in one of the patients who was positive by both tests (case 17) after 11 minutes of 10 per cent oxygen, and the test was stopped. One hundred per cent oxygen with cardiorespiratory stimulants was administered successfully. In another patient (case 9), negative by both tests, the anoxemia test was stopped after 12 minutes, because the patient showed generalized cyanosis that became progressively worse. One hundred per cent oxygen was again administered successfully. In addition, the anoxemia test was also stopped before completion in one patient who was negative by both tests, in two patients who were positive by both tests and in two patients who showed positive two step tests but negative 10 per cent anoxemia tests. A review of these five cases showed that in one (case 12) the anoxemia test was stopped after 18 minutes of 10 per cent oxygen, because the patient exhibited severe dyspnea; in another (case 14) the test was stopped after five minutes, because the patient complained of severe precordial pain; in another (case 15) the test was stopped after three minutes, because the patient complained of severe substernal and precordial pain; in another (case 18) the test was stopped after eight minutes, because the patient complained of marked precordial oppression; in the other (case 19) the test was stopped after 18 minutes, because the patient complained of severe precordial pain.

* The T wave height was recorded immediately after exercise and at the period of greatest anoxemia. The T wave height is given in millimeters; a diphasic T wave is recorded as "0."

In these five cases rapid administration of 100 per cent oxygen (which as previously explained is incorporated in the circuit) relieved the symptoms rapidly. In a short review of the anoxemia test as an aid in the diagnosis of coronary insufficiency Levy [4] mentions the precautions that must be taken before an anoxemia test is to be performed:

1. The control record should leave no doubt with regard to any recent myocardial infarction.
2. The test should not be repeated within 24 hours.
3. The test should not be done in the presence of congestive heart failure.
4. The test should not be done if cardiac infarction is known to have occurred within the preceding four months.

In none of the cases in this series were any of the above stated conditions present before the anoxemia test was performed.

COMMENT

Heart Rate.—The heart rate in the two step exercise test reached its maximum immediately on cessation of effort in all but two cases. In these cases the maximum was attained one minute after exercise. In some cases the heart rate rose slightly after a definite fall. Although the heart rate generally increased during the anoxemia test, the increase was not nearly so great as the increase that occurred after the exercise test. In some cases the cardiac rate fluctuated considerably during the entire period of anoxemia. The patient's nervous reaction to the test, with the associated reflex and sympathetic phenomena, must have played an important part in these fluctuations. Furthermore, variation in oxygen saturation or unsaturation of the blood during anoxemia [5] contributes to fluctuation in heart rate.

It is believed that the increase in heart rate after exercise is due in large part to decrease in vagal tone and to some extent to increased activity of the sympathetic nervous system.[6] Increased venous return through the Bainbridge reflex also tends to increase the heart rate after exercise starts.[7] In experimental work with dogs, Gasser and Meek [7] found that after destruction of the nervous system connections to the heart marked acceleration occurred after exercise. This observation tends to confirm the opinion that such factors as the direct action of epinephrine on the heart contribute to increase in heart rate after exercise.

During the anoxemia test the lowering of the oxygen tension in the inspired air causes decrease of arterial oxygen tension, with consequent lowering of oxygen saturation.[5] This effect is partly compensated by the increase in heart rate that results from decrease in vagal tone, increase in sympathetic nervous system activity and perhaps from direct action on the sino-auricular node.[8]

RS-T Segment and T Wave.—Exercise or anoxemia in a patient with diminished cardiac reserve due to coronary arterial disease intensifies existing abnormalities in the cardiac muscle. Changes may also be created in the physicochemical state of the myocardium when the work of the heart is increased, while its oxygen supply is decreased by inadequacy of the coronary blood flow. This condition exists in coronary insufficiency, which according to Master [9] "is a deficiency of the coronary circulation due to a discrepancy in the demands of the myocardium and its available oxygen or blood supply." Areas of ischemia with "injury" or "injury" alone may be created for a variable period with resultant alterations in the RS-T segments and the T wave of the electrocardiogram. These changes may not be related to pathological changes; they may be completely transient and "unattended by demonstrable structural changes." [10] The electrophysiological responses in and about the areas of ischemia and "injury" may have been changed by alteration of the normal depolarization and repolarization mechanism of the cardiac muscle.[11] Wolferth showed that trauma to the endocardium produced negative RS-T segment potential changes at the ventricular epicardial surface.[12]

The RS-T segment depressions and T wave changes that are the significant electrocardiographic alterations produced by the two step and anoxemia tests are generally seen in patients with involvement of the subendocardial layers of the myocardium. Schütz showed that moderate suction on the myocardium of the left ventricle, with the exploring electrode over the left ventricle on the chest wall, produced anoxemia of the subendocardium that resulted in RS-T segment depression in the electrocardiogram.[13] It is believed that the increased work of the myocardium following exercise and anoxemia causes the greatest and earliest strain on the subendocardium for the following reasons (Master,[14] Schütz,[13] Scherf,[15] Lepeschkin,[16] Puddu,[1b] Cabrera [17]):

1. The subendocardial layers are supplied by the terminal branches of the arteries.
2. These layers experience the greatest compression exerted on the myocardium during systole.
3. The duration of systole is longer in the internal than in the external layers of the heart. In effect, the papillary muscles that form part of the internal layers must relax last so that the valves hold until the end of systole.

In the electrocardiograms of normal persons taken after exercise the auricular T wave (T_a) becomes more

pronounced and may cause depression of the RS-T segment below the isoelectric line. This change is largely due to the tachycardia, but increased sympathetic tone may also play a part. It has, however, little importance in our results and those of others [5b] since the T_a wave has been shown to be very small at the rates produced by each test. Hyperventilation in the anoxemia test may be a factor in RS-T segment and T wave changes in the normal patient, since it is known that decrease in carbon dioxide content of the blood and the resultant alkalosis produce RS-T segment changes and T wave inversions.[18] The small amount of exercise demanded by the two step test has not in our experience caused sufficient hyperventilation to produce false positives. Likewise, acidosis may alter RS-T segments and T waves.[19] However, the slight shift toward blood acidity produced by formation of metabolites such as pyruvic acid and lactic acid, following exercise or anoxemia as carried out in the Master exercise and Levy anoxemia tests, has not been shown to be a cause of pathological alterations in the RS-T segment and T waves.

In our investigation the positive anoxemia tests have infrequently shown only T_4 inversions. Among the present series of 23 patients T_4 inversion was the sole alteration in only one of the positive anoxemia tests. This patient had, however, a positive exercise test, and a diagnosis of arteriosclerotic heart disease was made.

In an attempt to explain the normal results that anoxemia tests sometimes give in patients with known myocardial involvement, Malmström [5b] points out that these persons have a great capacity for increasing alveolar ventilation and thus keep their alveolar and arterial oxygen tension on a relatively high level during the test. This may explain the negative anoxemia tests that were obtained in five of our patients who had known myocardial disease and in one who later proved to have organic heart disease, all of whom responded positively to the two step exercise test.

It has been suggested by some authors that our criteria for a positive exercise tolerance test are too liberal. In recent review of the Master two step test Grossman, Weinstein and Katz [1g] concluded that 0.75 mm. RS-T depression or more in a limb lead and 1.5 mm. or more in a chest lead were more accurate criteria for a positive exercise test. Many other authors [20] have suggested that similar or greater increases in the depth of the RS-T deviations should be adopted as criteria for a positive test. They believe that with more liberal standards false positive tests will be rare. We are of the opinion that the more liberal the criteria the less sensitive will be the test and the less its value. In this connection it should be stressed that we employ as the zero line the central isoelectric level (P-R level) and not the control height of the RS-T segment. When the single two step test is negative the patient is given the double two step test, in which the number of trips and the time interval are doubled, so that the rate of effort remains the same. In a small proportion of cases in which cardiac disease was believed to be present in spite of a negative single two step test the double two step was of value in establishing the diagnosis.

SUMMARY

1. Twenty-three patients with normal resting electrocardiograms but with histories of precordial pain were given the two step exercise tolerance test and the 10 per cent anoxemia test. In the exercise test electrocardiograms were taken each minute for 10 minutes after exercise; in the 10 per cent anoxemia test electrocardiograms were taken each minute for 20 minutes during the administration of 10 per cent oxygen.

2. The most rapid heart rate in the two step exercise test was present in the electrocardiogram taken immediately after the exertion. In the 10 per cent anoxemia test there was no correlation between the period of anoxemia and the heart rate. The heart rate generally increased with the period of anoxemia but not so much as it did in the two step exercise test. Furthermore, in some patients the heart rate fluctuated considerably during the entire period of anoxemia.

3. RS-T segment depressions of over 0.5 mm. in the electrocardiograms taken immediately after the end of exercise were most frequent in lead 2, then lead 1, lead 4 and lead 3. Lead 4 showed the deepest depressions, then leads 2, 1 and 3 in that order. In the 10 per cent anoxemia test no correlation was present between the degree of RS-T segment depression and period of anoxemia; nor could any correlation be made of RS-T segment depression with the period of anoxemia and the time interval following the two step exercise test. This may be due to the varying oxygen saturation of the blood during the anoxemia test.

4. In both the 10 per cent anoxemia and the two step exercise tests the T wave is generally reduced in height; however, in a small percentage the amplitude of the T wave is increased. These changes could not be predicted in either test.

5. In this series the two step test was more sensitive and of greater diagnostic aid than was the anoxemia test. Positive two step tests appeared in the six patients who were known to have organic heart disease. The anoxemia test was negative in these six cases. Although a positive anoxemia test was considered reliable, a negative anoxemia test was not found to be dependable.

6. No untoward reactions occurred in any of the patients during the two step exercise test. During the anoxemia test a shocklike state developed in one of the patients, severe cyanosis in another and severe precordial or substernal pain in five others.

7. Examination of the material presented in this paper makes it apparent that there are many differences in the electrocardiographic responses produced by the two tests. They cannot be used interchangeably.

POTASSIUM DEFICIENCY IN BULBAR POLIOMYELITIS

Hyman S. Lans, M.D., Irving F. Stein Jr., M.D., Robert J. Becker, M.D., Archibald L. Hoyne, M.D.
and
Karl A. Meyer, M.D., Chicago

During the past several years there have been an increasing number of reports concerning potassium deficiency in many clinical conditions, including infantile diarrhea,[1] alkalosis due to intestinal and pyloric obstruction and vomiting,[2] and in many postoperative patients.[3] Our studies on potassium metabolism in surgical patients have led us to investigate many other conditions we believed might be associated with a deficiency of potassium. Three cases of bulbar poliomyelitis in which the electrolyte metabolism was studied are reported.

REPORT OF CASES

CASE 1.—A woman aged 29 was admitted to Cook County Contagious Hospital on Sept. 13, 1950, with a history of dysphagia of two days' duration. This dysphagia was manifested by inability to swallow, accumulation of saliva, and a "full feeling in the throat." Temperature was 102.4 F., pulse 100, and respirations 20. A nasal twang, slight redness of the pharynx, paralysis of the soft palate, and a moderate amount of accumulated secretion in the mouth were present. Nuchal rigidity was slight. Neuromuscular examination revealed a head drop but no apparent weakness of the extremities. Reflexes were normal. A diagnosis of bulbar poliomyelitis was made. Treatment consisted of placing the patient in the Trendelenberg position and intravenous administration of the usual fluids. On the following day the temperature had risen to 103.6 F.; and the bulbar symptoms were prominent, but there was no evidence of lower motor paralysis or respiratory difficulty. This course continued until Sept. 15, when cyanosis was noted and a tracheotomy was performed. On Sept. 16 the patient was afebrile; her color was good and her respiration strong, but she was still unable to swallow. Intravenous fluids were administered daily. On Sept. 19 the patient responded poorly and became cyanotic, and her respiration was shallow and irregular. A portable respirator was applied immediately, and oxygen was administered. The patient responded and her color returned, but she was markedly lethargic. Laboratory studies on this day disclosed the following: serum potassium 3.5 mEq. per liter (in our laboratory normal is considered 4.2 to 5.8 mEq. per liter), sodium 135 mEq. per liter, chloride 89 mEq. per liter and CO_2 combining power 77 volumes per 100 cc. Treatment with intravenous potassium chloride was instituted. Twelve grams of potassium chloride was administered on Sept. 19 and 20. Blood chemistry studies were performed daily, and on Sept. 21 the serum potassium was 5.0 mEq. per liter, sodium 138 mEq. per liter, chloride 98 mEq. per liter and CO_2 combining power 58 volumes per 100 cc. Clinically the patient was markedly improved. She asked to be removed from the respirator. Her respirations were regular and her color excellent, and less secretions were noted in the throat and pharynx. The patient continued to receive 4 gm. of potassium chloride intravenously daily until tube feedings were instituted. By Sept. 23 the patient was considered out of danger, and two days later the tracheotomy tube was removed. Tube feedings were begun and tolerated on the following day.

CASE 2.—A young woman aged 18 was admitted to the Cook County Contagious Hospital on Sept. 8, 1950, with fever, headache and difficulty in swallowing of two days' duration. A spinal tap was performed at another hospital and showed a pleocytosis consisting of 374 cells per cubic millimeter, predominantly lymphocytes. Physical examination revealed a very apprehensive white woman who was in no acute distress. Temperature was 104 F. (rectal); pulse, 88; and respirations, 22. There was a palatal deviation to the left and a left facial weakness. The neck was rigid. There was only a slight weakness of the left thigh muscles, but the reflexes were normal. A diagnosis of poliomyelitis was made, and therapy consisting of Trendelenberg position and parenteral fluids was instituted. This clinical course continued with some progression of symptoms to Sept. 14, when the patient was afebrile. At this time she had a marked left facial, hypoglossal, iliopsoas, and quadriceps paralysis and right gluteus medius weakness. Treatment consisted of physical therapy, hot packs, and intravenous fluids. On Sept. 19 the serum potassium was 3.9 mEq. per liter, and the sodium, chloride, and the CO_2 combining power were normal. Treatment with intravenous potassium chloride was instituted. On that day and the following day she received a total of 14 gm. of potassium chloride. On Sept. 21 the serum potassium was 4.7 mEq. per liter and the patient was much improved. She was clearer mentally, stronger, and more cheerful, but still unable to take oral fluids. Two grams of potassium chloride was administered daily until Sept. 25, when gavage feedings were instituted.

CASE 3.—A boy aged 9 yr. was admitted to the Cook County Contagious Hospital on Sept. 19, 1950, with a history of fever, lethargy, and weakness of the left leg. Two days before admission the patient began vomiting, and his mother noted a nasal twang to his voice. Physical examination revealed an extremely lethargic white boy, whose temperature was 101 F. (rectal); pulse, 100; respirations, 30. The patient had a head drop, a marked nuchal rigidity, and positive Kernig's and Brudzinski's signs. There was some pharyngeal weakness, but other reflexes were normal. Spinal tap revealed 56 cells per cubic millimeter, 60% of which were lymphocytes. Treatment consisted of parenteral fluids and Trendelenberg position. On Sept. 21 the serum potassium was 3.9 mEq. per liter, and potassium therapy was instituted. On Sept. 21 and Sept. 22 he received a total of 8 gm. of potassium chloride. The serum potassium on Sept. 23 was 4.6 mEq. per liter, the patient was afebrile, his sensorium was clear, and he was able to take oral nourishment.

These patients were unable to swallow due to the pharyngeal paralysis. Two of the patients had received the usual parenteral fluids without potassium for at least 10 days. The patients showed marked loss of strength and energy and were listless and lethargic. They were treated with intravenous potassium chloride. Twenty-four hours later the clinical condition of all three patients had markedly improved; lethargy and listlessness were absent and their energy had increased a great deal. This clinical response was dramatic. The marked improvement was obvious to all members of the medical and nursing staffs, and the patients themselves commented on their increased strength and sense of alertness.

The three cases of bulbar poliomyelitis reported are from the services of Drs. Leichenger, Hoyne, and Rosi.

COMMENT

Paralysis of the pharyngeal musculature is very frequent and troublesome in patients with bulbar or encephalobulbar poliomyelitis. This results in difficulty or inability to swallow, associated with regurgitation. The inability to swallow necessitates the use of intravenous and subcutaneous fluids to provide nutrition and prevent dehydration. Dehydration in patients involves not only the problem of water depletion but an imbalance of electrolytes. Since patients with bulbar poliomyelitis often require prolonged parenteral alimentation, the electrolyte and fluid balance of these patients becomes important.

The usual parenteral solutions contain little or no potassium; therefore, patients sustained on these fluids alone receive inadequate potassium. In addition, solutions containing sodium chloride without potassium, increase the renal excretion and further deplete the body store of potassium.[4] As a consequence of the reduced intake of food, the oral intake of potassium is decreased. Thus, the continued loss through vomiting,[5] and daily urinary excretion,[6] without adequate intake, leads to potassium deficiency. In dehydrated patients the serum potassium level may be normal even though a severe cellular deficiency is present; after these patients are hydrated, a low serum potassium is often found. Certain signs and symptoms are known to be associated with a potassium deficiency,[7] including loss of strength and energy, listlessness, and anorexia. Weakness of the extremities develops and progresses to flaccid paralysis. Sometimes an ascending or Landry's type of paralysis may be present. Cranial nerves are rarely involved. Weakness of respiratory muscles is often marked; paralysis of the intercostal muscles and diaphragm may be present. Breathing becomes rapid and shallow, and use of accessory muscles and gasping respiration become evident. In the absence of prompt potassium therapy, respiratory paralysis and death may ensue.

Patients with bulbar poliomyelitis have a limited respiratory reserve and must be watched closely and carefully for evidence of respiratory failure. Any condition which further decreases the patient's ability to breathe will increase the mortality. Weakness and paralysis of respiratory muscles are often present in potassium deficiency. Patients with bulbar poliomyelitis cannot tolerate the superimposed symptoms of a potassium deficiency. Therefore, adequate intake of potassium must be provided these patients to prevent the occurrence of these additional symptoms.

Excellent reviews of potassium deficiency and its treatment have been presented by Bodansky,[7a] Randall,[2b] Danowski,[7b] Darrow,[7c] and Elkinton and Tarail.[6a] Solutions containing varying concentrations of potassium salts have been advocated by these authors and we are investigating the use of these solutions. In patients with renal insufficiency or dehydration, administration of potassium salts must be cautiously given and only under constant and proper clinical and laboratory supervision. Rapid intravenous injection of concentrated solutions may lead to a high serum level which is toxic to the heart and cause heart block and cardiac arrest. It is necessary to regulate the rate of introduction to avoid a toxic level of potassium in the serum. Therefore, at present, a solution containing 2 to 3 gm. of potassium chloride in a liter of normal saline, 5% or 10% dextrose or amino acids, is recommended for general use. This solution should be administered not faster than 8 to 12 cc. (120-180 drops) per minute.

The patient with bulbar poliomyelitis should receive daily adequate amounts of intravenous fluids containing dextrose, sodium chloride, and amino acids in order to maintain hydration, electrolyte balance, and nutrition. When potassium deficiency is found to be present, 2 to 3 gm. of potassium chloride should be added to each liter of intravenous fluid so that the patient receives 6 to 12 gm. of potassium chloride a day.

This treatment is continued until the serum potassium level has been normal for 24 hr., after which 4 gm. of potassium chloride should be administered daily to provide a minimal daily intake of potassium. Most foods are a good source of potassium; therefore, parenteral potassium therapy is no longer needed after the patient can be fed.

SUMMARY AND CONCLUSIONS

Three patients with bulbar poliomyelitis were found to have a potassium deficiency. Treatment of the existing deficiency with intravenously administered potassium chloride resulted in a marked improvement of their condition.

Patients suffering from bulbar poliomyelitis who are unable to eat will develop a potassium deficiency unless adequate potassium intake is provided. Severe, prolonged potassium deficiency can be lethal. This condition when present in patients with bulbar poliomyelitis may be a contributing factor in the high mortality rate. Proper treatment of electrolyte imbalance in these patients is essential and must include adequate potassium therapy. Further studies are indicated concerning the relationship of potassium deficiency to the clinical picture and mortality of poliomyelitis.

ADDENDUM

Since preparation of this report, three additional patients with bulbar poliomyelitis were found to have a marked hypopotassemia. Institution of intravenous potassium chloride therapy resulted in a prompt and definite clinical improvement in all three patients.

TREATMENT OF UREMIA BY PERFUSION OF AN ISOLATED INTESTINAL LOOP

SURVIVAL FOR FORTY-SIX DAYS AFTER REMOVAL OF THE ONLY FUNCTIONING KIDNEY

E. E. Twiss, M.D., Rotterdam, The Netherlands
and
W. J. Kolff, M.D., Cleveland

In 1946, de Leeuw and Kolff[1] treated a patient with contracted kidneys and uremia by dialysis through an intestinal loop. A loop of small intestine was separated by transverse sections and the ends brought out through lateral stab wounds, leaving the vasculature intact. The continuity of the remaining intestine was restored by end-to-end anastomosis. The isolated intestinal loop was perfused. Rinsing fluid from a reservoir was let into the proximal end of the intestinal loop after passage through a Murphy drip and through a thermostatically controlled bath to bring it up to body temperature. From this first patient 5 gm. of urea could be removed in 10 hours of perfusion.

Since then, all our patients with severe chronic uremia were treated with a forced high-caloric, low-protein diet according to the principle of Borst. Conditions demanding intestinal dialysis rarely occurred.

Odel and Ferris,[2] Seligman, Frank and Fine,[3] and Ask-Upmark[4] in Sweden have also attempted to treat patients by intestinal dialysis. While the outcome in these patients and in ours was for various reasons unsatisfactory, enough evidence has accumulated to establish the fact that intestinal dialysis can remove sufficient urea to maintain urea balance. White and Harkins[5] concluded that irrigation of intestinal loops would remove fairly large amounts of urea, but it did not prolong the life of the nephrectomized animals because of severe disturbance in the electrolyte pattern of the blood. It is therefore most important to find a rinsing fluid that will not disturb but will even correct the patient's water and electrolyte balance.

Visscher[6] and his group confirmed the conclusion of Heidenhain that forces other than those of normal osmosis determine the rate of water transport, and they prove that sodium chloride can move into the blood against a large concentration gradient, but solutions from which there was a significant water absorption were definitely hypotonic.

We[7] have performed more than 200 intestinal perfusions on dogs in order to find a suitable rinsing fluid. A concentration of 100 to 200 mg. per 100 ml. of sodium chloride in the lavage fluid usually prevented chloride absorption or excretion by the intestinal mucosa when the flow rate was 1 to 1.5 L. an hour. To prevent water absorption, the lavage fluid had to contain substances which are absorbed slowly or not at all by the intestinal mucosa (such as sucrose or magnesium sulfate). The composition of the lavage fluid had to be such that it was isotonic with or slightly hypertonic to plasma. Like Claus Brun in Copenhagen,[8] we compared the freezing point depression of plasma and lavage fluid, taking care that the freezing point of the lavage fluid was never below that of the blood plasma. Potassium and calcium salts were added to prevent calcium and potassium loss during lavage.

REPORT OF CASE

On March 15, 1949, a right nephrectomy was performed on a 36 year old man for infected hydronephrosis. Anuria followed, and the patient was transferred to our hospital. On cystoscopic examination, it proved impossible to pass a catheter through the ostium of the left ureter. After 10 days of practically complete anuria, an exploratory laparotomy was done. The left kidney region was found to be empty. A small piece of tissue could be felt at the level of the third lumbar vertebra. Since it was concluded that there was no adequate remnant of kidney, a loop was prepared from 2.5 m. of the midsection of the small intestine, and the two orifices were sutured into the abdominal wall. The continuity of the remaining intestine was restored by end-to-end anastomosis. Data on this patient are shown in charts 1 and 2.

Diuresis.—The left aplastic kidney was able to produce some urine. The total amount of urine produced over 46 days was 6.4 L., or 140 ml., a day. The total urea excreted in the urine was 28 Gm., or 0.6 Gm. a day.

Blood Urea.—There was a steady rise of blood urea, which increased to 369 mg. per 100 ml. on the sixteenth day after the nephrectomy. This level was lowered a little by cautious daily perfusion through the intestinal loop from the 16th to the 18th day. The patient was treated with the Kolff rotating artificial kidney on the 19th and the 24th day after nephrectomy. Seventy-two and 53 gm. of urea, respectively, were removed by these procedures, and the blood urea was reduced to 167 mg. per 100 ml.

On the 29th day a new series of perfusions through the isolated intestinal loop were performed. As may be seen from chart 1,

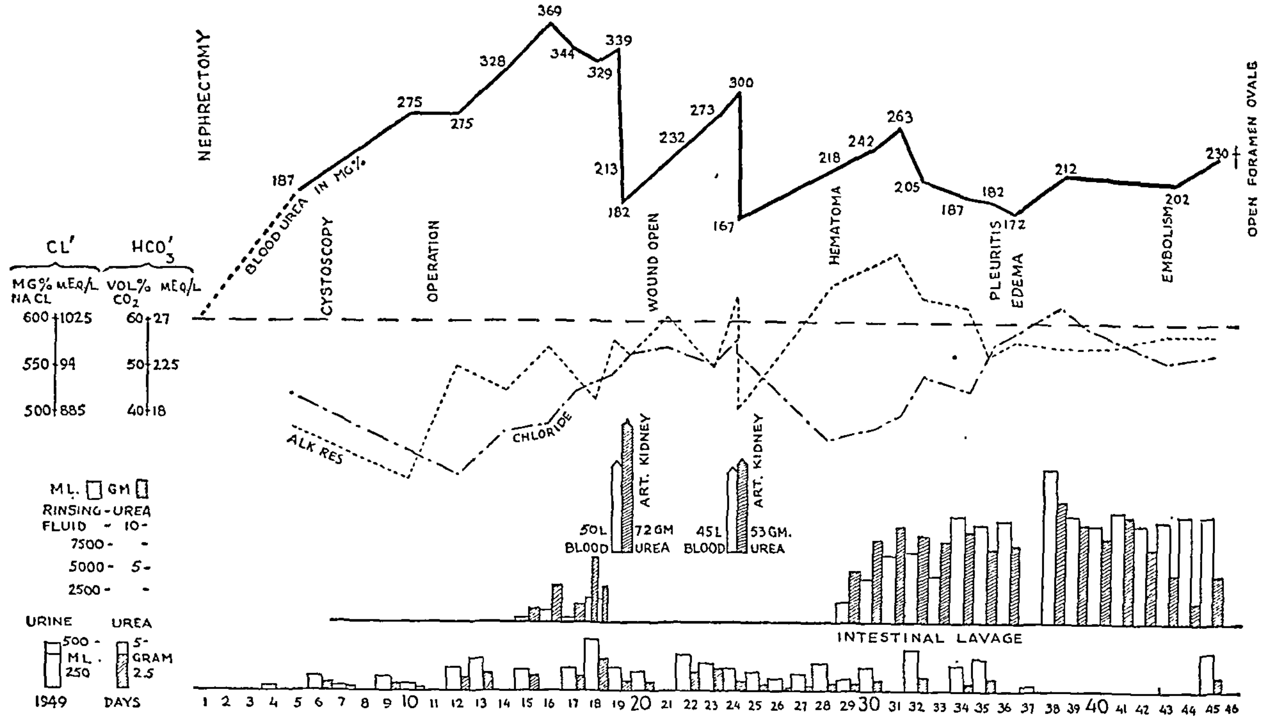

Chart 1.—A 36 year old man had his only functioning kidney removed on the day when the first point of this graph begins. His blood urea in mg. per 100 ml. is shown in the broken line. *Note that it was twice reduced by treatment with the artificial kidney and that it stayed about 200 mg. from the* 32d to the 45th day. On the lowest line the unshaded blocks indicate the total amount of urine produced each 24 hours by the patient's aplastic left kidney (an average of 140 ml. a day), and the shaded blocks indicate the total amount of urea excreted by this kidney (an average of 0.6 gm.). On the second line from the bottom the unshaded blocks indicate the amount of rinsing fluid that perfused the isolated intestinal loop and the shaded blocks indicate the amount of urea removed in one dialysis (an average of 8.6 gm. per 10 hours). - - - - - indicates the normal average value of blood urea, plasma chloride, and alkali reserve; -.-.-.-.-.-. indicates Cl-, and .... HCO_3-.

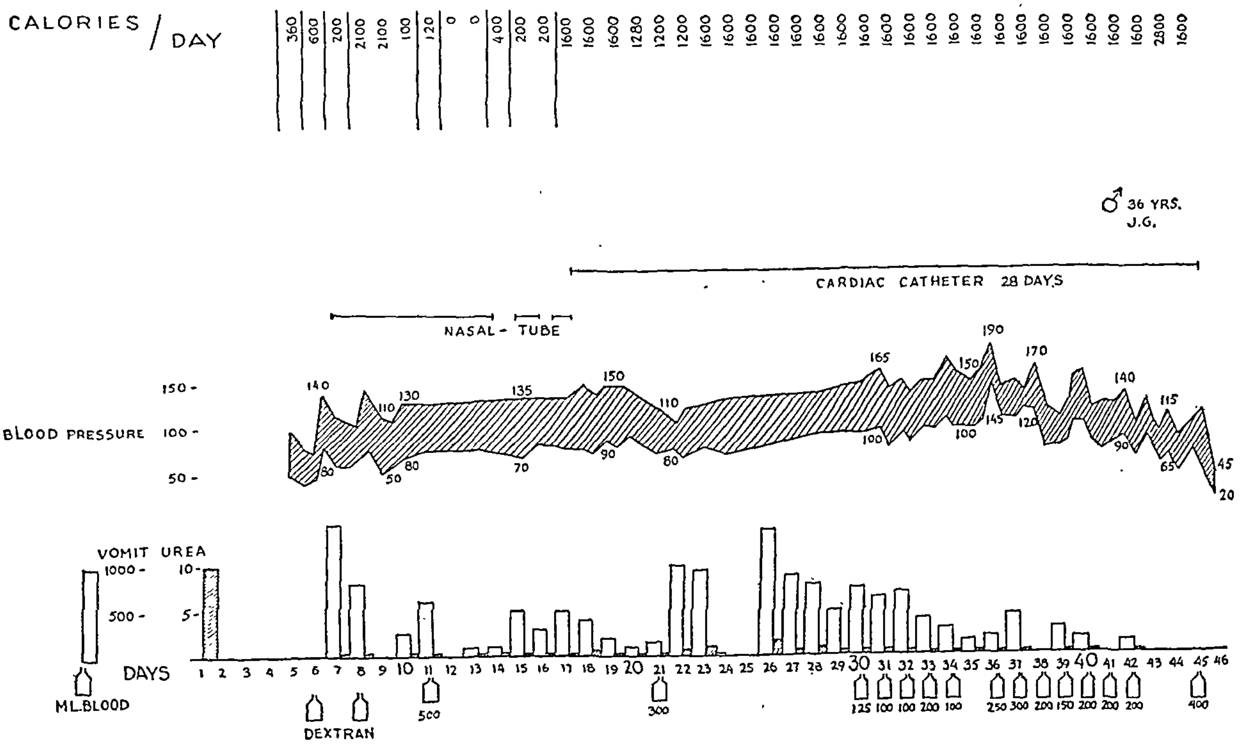

Chart 2.—This is a graph of the same patient as in chart 1. The same number of days after nephrectomy is shown at the bottom of the graph. The bottles indicate infusions with dextran, blood or amigen to counteract low blood pressure. Unshaded blocks indicate the amount of vomitus. Vomiting decreased after 36 days. The negligible amount of urea found with vomitus is indicated by shaded blocks. The blood pressure as indicated by the shaded area rose to 190/145 when the patient had edema, but decreased when water and sodium were withdrawn. Calories per 24 hours, given by mouth, tube or cardiac catheter, are shown at the top. The considerable amount of calories resorbed from the intestinal loop has not been taken into account.

the blood urea fell from 263 to 172 mg. per 100 ml. and was kept at a level of about 200 mg. until shortly before the death of the patient. He suffered from complete anuria during nine of these last 16 days.

Dietary Treatment.—It proved impossible to feed this continuously vomiting man with a butter-and-sugar diet according to Borst's principle. Feeding by gastric tube was attempted, but even this proved impractical. The amounts of vomitus are recorded in chart 2. The amounts of urea removed with the vomitus proved to be negligible. On the 17th day after the nephrectomy, a thin polyvinyl plastic cardiac catheter was inserted to feed the patient with 1 l. of 40% dextrose a day, to which were added heparin sodium (100 to 200 mg.), insulin, penicillin, vitamin C and vitamin B complex. In this way, with 1 L. of 40% dextrose, 1,600 calories could be provided every 24 hours without the risk of overloading the patient with fluid (deKeyser, Van Eekhoutte, Kop and Kolff).[9] Moreover, sodium chloride and sodium bicarbonate could be added as seemed necessary. The cardiac catheter was left in place for 28 days. No signs of local irritation were observed. The patient's general condition was fair except for vomiting, but the latter state improved gradually on the 36th day.

Composition of Rinsing Fluid for Intestinal Dialysis and Absorption or Excretion of Water and Chloride

Days After Nephrectomy	Composition of Rinsing Fluid, Mg./100 Ml. NaHCO₃	KCl	$CaCl_2$	NaCl	Sucrose	Dextrose	$MgSO_4 \cdot 7H_2O$	Osmotic Pressure Calculated in Milliosmols per L.	Fluid Absorbed or Excreted, Ml.*	Chloride Absorbed or Excreted, Gm.*	Urea Excreted, Gm.	Flow, Ml./Hr.

* A indicates absorption; E, excretion.

Complications.—On the 20th day there was disruption of the laparotomy wound, and it had to be sutured. This event forced us to postpone intestinal perfusion until the 29th day. On the 28th day, a hematoma developed in the abdominal wall; it may have been due to the constant vomiting and the necessary heparinization. The heparin dosage was temporarily decreased. This may have permitted the formation of small thrombi along the catheter. These thrombi probably gave rise to small emboli, which accounted for some pulmonary symptoms. More serious, however, were small emboli which first appeared in the legs and hands, reminiscent of those in bacterial endocarditis. On the 42nd day the patient suddenly became unconscious and new emboli were observed in the hands and feet. When he awakened he was partly paralyzed and for some time aphasic. We still did not dare to remove the cardiac catheter, although feeding could be performed by way of the intestinal loop. There was no other method of supplying daily infusions of blood, dextran and a protein hydrolysate (aminosol or amigen®) needed to sustain the blood pressure, which showed a tendency to fall. Since embolism continued, the catheter was removed on the 45th day. The patient became comatose and died the day after. At autopsy there were slight generalized edema and arterial emboli in the hands. The left kidney was hypoplastic and hydronephrotic. Its length was 6 cm. The renal cortex was atrophic and 1.5 mm. broad. The left ureter was dilated above and constricted in its course through the bladder wall. A long thin cylindrical thrombus was present that contained a lumen large enough to pass the catheter and indicated where it had lain in the veins and in the right auricle. Apart from this thrombus, the endocardium presented a smooth and undamaged surface. An open foramen ovale explained how emboli from the catheter thrombus entered the greater circulation. (Afterward we heard that three years previously the patient had suffered from a sudden attack of unconsciousness, which then was also thought to be a cerebral vascular accident.) The right kidney was absent. There was an old hemorrhage in the left adrenal gland.

COMMENT

Urea.—Chart 1 shows that during the period of daily intestinal perfusion from the 30th to the 46th day, the blood urea was maintained at a level of about 200 mg. per 100 ml. Over a period of 16 days (with one day's rest), 134 gm. of urea was removed, or an average of 8.6 gm. a day during 8 to 10 hours of perfusion.

Creatinine and Uric Acid.—The amount of creatinine removed was about 6.8% of that of urea, and the amount of uric acid, 4.8%. As the concentrations of these substances in the blood plasma amounted to 7% of the concentration of blood urea, we may assume that they were eliminated probably almost as well as was the urea. The creatinine and uric acid in the blood did not show any increase during the 40 days of observation.

Water and Sodium Chloride.—Our observations with the dog, on which a comparatively short ileac loop was used, led us to select for this patient a perfusion fluid that proved unsatisfactory, probably because the loop was much longer. During the four days of perfusion (30th to 34th days inclusive), a total of 8 L. of water was absorbed during the dialysis (table). Further absorption of water was prevented by increasing the osmotic pressure of the rinsing fluid by the addition of sucrose, dextrose or magnesium sulfate. Water was now withdrawn, while sodium chloride was still absorbed (10, 9 and 6 gm. a day). The plasma chloride rose to a normal value, and, as vomiting stopped and the patient was allowed to drink, edema appeared. During this first period of eight days, a total of 72 gm. of sodium chloride had been absorbed. We then decided to remove both the edema and the excess of salt by perfusion. This was accomplished by maintaining the osmotic concentration of the rinsing fluid at its former level while at the same time decreasing its content of sodium chloride first to 0 and then to 50 mg. per 100 ml.; potassium chloride, calcium chloride and sodium bicarbonate were not changed. From the 34th to the 45th day, 16 L. of fluid were eliminated. This demonstrates that it was possible to obtain a "diuresis" of 1.5 L. a day through this intestinal loop. From the 38th to the 45th day, 48 gm. of sodium chloride was excreted by the intestinal loop, an average of 6 gm. per day.

---

[9] de Keyser, R.; Van Eekhoutte, P.; Kop, P. S. M., and Kolff, W. J.: Feeding Through Cardiac Catheter with 40 Per Cent Glucose Solution in Treatment of Very Severe Uremia and Other Conditions Associated with Persistent Vomiting, Nederl. tijdschr. v. geneesk 93:2386 (July 16) 1949.

Arterial Pressure.—During the period of positive chloride balance, the blood pressure rose to hypertensive levels (chart 2). With withdrawal of sodium chloride through the loop, the pressure fell slowly to normal and then to hypotensive levels. This patient was virtually bilaterally nephrectomized, so that it is possible that his "sodium-responsive" hypertension was not of renal origin. The apparent sensitivity of the nephrectomized subject to the pressor effects of excess sodium may account for the hypertension observed in nephrectomized dogs submitted to blood dialysis against a sodium-rich medium.[10]

Potassium.—Since the patient had a high serum potassium (33 mg. per 100 ml.), no potassium was added to the rinsing fluid at first and from 0.8 to 2.4 gm. of potassium was removed a day. The serum potassium dropped to 17 mg.

Sodium Bicarbonate.—Sodium bicarbonate usually was absorbed from the rinsing fluid. It was possible to keep the carbon dioxide-combining power at a normal level by using sodium bicarbonate from 200 to 66 mg. per 100 ml.

Calcium.—Calcium was nearly always added to rinsing fluid (calcium chloride, 28 mg. per 100 ml.). This prevented both significant absorption and loss of calcium.

Sugar.—Dextrose is a substance that is rapidly absorbed, whereas sucrose is absorbed only after enzymatic hydrolysis. Consequently, sucrose or a mixture of sucrose and dextrose was added to the fluid. Nevertheless, 300 to 400 gm. of dextrose was often absorbed. Consequently one day's perfusion provided 1,200 to 1,600 calories plus a small volume of water of oxydation.

Local Effect.—We never saw any irritation of the skin even after prolonged contact with the dialyzing fluid. The local effect was limited to irritation of the mucosa of the loop when a strongly hypertonic fluid was used. Care should be taken to avoid decubitus of the stomata by inflow or outflow tubes. It is well to bear in mind that de Peyster and Straus[11] produced multiple mucosal ulcerations with continuous perfusion of an ileal loop in dogs, using 20% sucrose-Tyrode solution. We have not used such high concentrations and have avoided continuous dialysis over a period longer than 70 hours.

As a result of our experience in this case, we suggest the following general formula for the rinsing fluid in an isolated intestinal loop:

Glucose	0-3.6%
Sucrose	6-8%
Sodium chloride	0-150 mg./100 ml.
Potassium chloride	0-40 mg./100 ml.
Calcium chloride	0-28 mg./100 ml.
Sodium bicarbonate	100-200 mg./100 ml.

This formula can be modified according to the special features of the patient to be treated. Sucrose can be partially replaced by $MgSO_4.7H_2O$, 2 per cent. The use of carbomethylcellulose is being studied at present.

SUMMARY

A man 36 years old was hospitalized for 46 days after removal of his only functioning kidney. He was kept in urea balance by dialysis through an isolated intestinal loop for 16 consecutive days. In this patient the blood pressure varied in proportion to the sodium chloride and water balance. Salt and water balance could be maintained by appropriate adjustment of the composition of the rinsing fluid. The rinsing fluid should usually be hypertonic and should not contain more than 150 mg. sodium chloride per 100 ml. As a result of study of this patient, a more useful rinsing fluid has been developed.

Discarded Theories and Treatments.—It is salutary to look back in Medicine. Its path is strewn with discarded theories and treatments which held the field for short and credulous periods; and when some are thrown up again by the whirligig of time, a knowledge of the part which they have played in the evolution of our ideas is always helpful. It is often chastening. When orthodox medicine fails, unorthodox methods appear; and that is easy enough to understand. What we often do not recognise is the frequency with which ill-founded theories become accepted by the orthodox, and how ideas of slender foundation may dominate for a time a whole branch of medicine. The fact that ideas or treatments have been discarded does not mean that they were ill founded or completely without results. They may have been followed by better ideas or treatments. Sometimes they are unjustly displaced, and in the process much that was good becomes forgotten.—C. Cameron, M.D., Fads and Fancies: Thirty Years of Tuberculosis, *Lancet*, April 14, 1951.

SPECIAL ARTICLE

CITIZENSHIP—A PHYSICIAN'S OBLIGATION

Ernest E. Irons, M.D., Chicago

American freedom or socialistic enslavement—which shall it be? A decade or so ago, most citizens would have been shocked that any sane person should dare to ask such a question. Liberty and opportunity were the substance of our social, political, and economic tradition. True, the increasing complexities of urban life with its rising standards of living and the impact of world troubles constantly imposed new problems to be solved and new social injustices to be corrected, but, despite these difficulties, we continued to enjoy our American freedom and assumed that our birthright could never be taken away.

The vast and increasing confusion in which the American people now are groping would have been inconceivable to the average intelligent citizen thirty years ago. We had made mistakes, but our former national common sense saved us from catastrophic accidents. Our departure from sound economics and honesty can be explained only by a growing disregard for moral values in business, in labor, in politics, and in our relations with our fellow men. Never before has public confidence in our administrative political leaders fallen to so low an ebb as now.

After years of at times deceitful planning, the promoters of the Socialist Welfare State decided that the public and some members of Congress were sufficiently misinformed and confused to ensure the enactment into law of the nationalization of medicine. This attempt to take a long step down the Socialist road to communism failed, but only because patriotic democratic members of Congress broke with a misguided federal administration and refused to accede to this socialistic regimentation of their countrymen. Socialization of medicine was again made an issue in the congressional elections of 1950, but by this time many of the misstatements of socialistic bureaucrats had been exposed by a vigorous campaign of education. As a result, sound thinking triumphed over personal political expediency.

SOCIALISTIC DEGENERATION IN MEDICINE AND GOVERNMENT

The education of the American people in matters medical is now well begun. Apparently the election of Nov. 7, 1950, made clear the opinion of the voters on the issue of socialized medicine. The more they learned about it and observed its working in England, the less they wanted it. Physicians themselves became more aware of what medicine in a free economy had accomplished and of how political medicine would impair the quality of medical service to their patients, the public. The assumption by government of the supervision of the health and private lives of citizens is an early and, in the past, successful Marxian technique in the socialization of the state.

Socialized medicine was only one of the issues in this campaign, but it was one which the voters when fully informed could understand. Health and liberty of choice are closer to men's hearts and lives than the more abstract but equally important issue of the impact of socialism on government. The roots of socialism in this country have spread far beyond medicine, deep into many phases of our national life.

Physicians had been expected to attend principally to their profession, and this they traditionally, and perhaps unfortunately, had done. In self-defense and in the interest of the welfare of the public they were now suddenly propelled into medicosocial problems with which they should have been more conversant, and then into the midst of political combat in which they were inexperienced. They saw ruin of medical care of their patients, as well as national financial disaster through reckless spending, advancing on the professions and on business institutions. They saw the progressive loss of freedom in a nation dedicated to free enterprise and individual responsibility and incentive. They began to stir and to awaken colleagues and neighbors to their personal responsibility as American citizens. In many communities they, as citizens, took a leading part in elections; in some, their efforts determined the outcome; in others, the medical contribution was a minor but, nevertheless, a significant factor in determining the result of this first battle. The election of Nov. 7 proved that citizens could be aroused by a realization of the increasing regimentation of the nation.

Now, as a citizen, the physician must look about him and try to determine what has happened to him and his fellow citizens that freedom of the individual should thus be threatened. He knows that he is not an economist, nor a statesman, nor a financier, nor a philosopher. But he is deeply interested in human welfare and in both the medical and economic care of the unfortunate. At the same time, he recognizes the danger of moral pauperization in the attempt to relieve physical poverty. He is aware of the conflict between superficially attractive Utopian proposals to "furnish free medical care" to everyone, and the inevitable violation of personal liberty and deterioration of quality of service which will result from their implementation. His medical training has taught him to look behind the symptoms of a disease for the causes which have produced it. He may be unable to determine all the causative factors, but, in any case, he can find some of them and, by their correction, prevent further damage and happily contribute to the recovery of his patient.

THE ILLNESS OF GOVERNMENT

Let us look at the government of our country as a patient. Clearly it is not in good health. What has the patient done to impair his health? What habits has he acquired that have contributed to his present illness? What changes have occurred in his environment, per-

---

Read at the Annual Meeting of the Illinois State Medical Society, Chicago, May 23, 1951.

haps, in part, through no fault of his own, that have weakened him? How serious is his sickness? Can he recover? Some of these questions the physician may well refer to his consultants, the statesman and economist. Evidently our national ill health is due to many causes besides the medical. However, some of the early departures from sound thinking involve sociomedical questions, and so it may not be amiss for a physician to recall some of those now forgotten events. Some of the later ones are neither creditable nor palatable. The average man has an extremely limited knowledge of history and a deplorably short memory. One of the chief assets of the demagogue is the proneness of people to believe what they are now told and to forget what really happened a few years before. Our return along the hard road back to sanity and safety may be assisted by a look backward at early and at first unrecognized deviations from right and justice.

ECONOMIC AND SOCIAL CHANGE

Our relations with each other in families, neighborhoods, cities, and in the nation are continually subject to change. With economic changes, population shifts and occupations change. Invention, machinery, and the division of labor have increased the density of population in cities and have created new problems for workers and employers. The cities themselves are undergoing continuous change in the character of their several districts.

But in the effort to remedy old or new defects in our civilization, we must explore carefully the ultimate effects of new social remedies. Such caution is not reactionary; rather, it ensures real progress. Social crises are created when changes in economics are sudden and so widespread that masses of people are unable to adjust themselves to them. At such times, new theories of procedure are suggested, some of which are good; others are bad because the means employed for attempted correction may yield temporary benefits, but later create new distress. Alluring bait is offered in large print; heavy penalties are concealed in small type.

Our nation has survived many political and economic crises since the Civil War. The Greenback era, free coinage of silver, Populism, and the unrest typified by Coxey's Army appeared from time to time as national problems. Each originated in a time of economic stress in a misguided attempt to accomplish a needed reform. Each appealed to an emotionally excited bloc whose leaders were perhaps uninformed of the total effect of their proposals, or else they ignored the national interest to secure personal advantage. Each of these issues was resolved on the basis of national common sense.

In America we withstood the wreckage of postwar inflation which paralyzed some of the nations of Europe. However, we embarked on a program of speculation. Money was mistaken for wealth. Unsound and dishonest procedures crept into business, and as a nation we worshiped Mammon. Substantial business men, enchanted by the vision of easy money, lost their economic poise. Our social values were impaired still more than our economic standards.

The answer came in the financial crash of 1929. This financial disaster was part of a world-wide financial collapse, which in some countries preceded, and in a few, followed, our own. Fortunes of the rich were swept away along with the savings of the thrifty wage earner. Discouragement and frustration pervaded all walks of life. People demanded a change, not caring greatly what its nature might be.

POLITICAL IMMORALITY

At this point our elected governmental officials failed us. They campaigned for economy and yet, when elected, they introduced excessive waste. They sacrified honest action to political advantage. They employed measures which appeared to provide temporary help to the poor and financially distressed man, but at the same time they took away from him his initiative and sense of responsibility to help himself. Many citizens have not even yet recovered their sense of economic and personal responsibility.

To loss of popular respect for law was added loss of governmental respect for the Constitution. When the Supreme Court withheld approval of some New Deal proposals, it was attacked by the administration and the attempt was made to replace its members by those more complacent with the new philosophy. Administrative regulations were devised to circumvent constitutional law. The democracy of our republic, based on the concept of the freedom, dignity, and personal responsibility of the individual citizen, was disregarded.

In 1934 a Cabinet officer stated, "A wonderful opportunity lies ahead of us under our national leadership, not only to consolidate all the social gains to date but to make further substantial advances. . . . It is necessary to modify or even to discard certain social, economic and political concepts appropriate to a pioneer people . . ." In 1945 spokesmen for the Federal Security Administration revealed their program in balder terms, stating that "Social security and public assistance programs are a basic essential for attainment of the socialized state . . ." This statement was reprinted in 1949 and recently again distributed. Distribution is reported to have been discontinued in 1951, only after repeated criticism by the medical profession.

That we have survived thus far is a tribute to the original sturdiness of the nation.

In such an atmosphere, and with such contempt for the principles that our fathers expressed in the Constitution and that we had lived by for 120 years, it is small wonder that economic standards and morality in government and in the lives of the ordinary citizen declined still further. Rigid honesty was replaced by willingness to compromise, and the nation, having lost its guiding compass in domestic matters and, later, in international dealings, was prepared to travel further down the Socialist road.

World War II found us better served technologically than in World War I. We carried on the war successfully, but, because of our moral deterioration, we failed to win the peace. Socialism and communism had infiltrated government departments, and traitors sat in high places. Public confidence in the integrity of government departments was shaken.

SOCIALISTS AND INTELLECTUALS

The significance of intrusions of government into the private lives of citizens by regimentation of a formerly free economy and by a subtle imposition of a planned economy through subsidies is not even now understood by the people. They feel that things are not right, but do not always understand why. Following the well-known pattern of Marxism, Socialist propagandists gathered about them a company of people, some of whom had acquired prominence in their own fields of science or letters but had little real knowledge of the fundamentals of economics or government. To this group, often called the intellectuals, was added a miscellaneous fringe of flabby-minded joiners. Socialism acquired its fellow thinkers as communism had its fellow travellers.

Full-fledged Socialists formed the directing core of the intellectuals and set about molding the opinion of the masses, who were themselves unable to form intelligent judgments. A large proportion of the fellow-thinking intellectuals were equally unqualified to form sound opinions. It sufficed to them to believe that their views were their own, rather than those implanted by their Socialist leaders. They became "second hand dealers in ideas."

"Intellectuals" is a convenient term to describe this coterie, but it should convey no personal connotation of opprobrium other than that many allow themselves to be made the unknowing tools of propaganda to divert public opinion from support of constitutional government. Some, no doubt, derive satisfaction in basking in a fleeting and undiscriminating public acclaim of their pronouncements, the soundness of which is not supported by actual knowledge. While they profess to be liberal they are actually being gullible. They do not intend to be unpatriotic, but their actions appear to belie their plea of patriotism.

EDUCATION OF AMERICAN CITIZENS

The education of our citizenry to the dangers of socialism has already begun and must be continued. Through this education, we, as physicians, may also learn. This is our most important national issue, in which all elements of our national life—manufacturing, banking, business, labor, agriculture, together with medicine and the other professions—are vitally concerned. The very existence of our two-party system, in which we believe, is at stake. We have a right to be proud of our country, its resources, its freedom of the individual, and its Constitution which guarantees this freedom. Our American Constitution is unique and provides opportunity, justice, and freedom to each citizen in a free enterprise system. It was intended to be unique, and, under it, freedom need not "perish from the earth."

We are proud to be citizens under this system. It may have some faults, but under it we enjoy the highest standard of living yet attained in the world. And for this we offer no apology.

We need not cringe at the Communist pronouncement that capitalism and communism cannot coexist in the world. If this be true, then it will not be capitalism and personal freedom that go down. Communism and socialism have within them the elements of revolution and violence which, as in the past, will effect their own downfall.

Some patriotic and relatively well-informed citizens now seem to doubt whether we can ever escape from the domination of bureaucracies which we have allowed to grow up in our government, or, indeed, can long withstand the pressures of our socialistic and communistic enemies. Such faint hearts need only recall the period 1840-1860, when other good people doubted the possibility of abolishing physical human slavery and preserving the Union.

Bureaucratic and socialistic enslavement of the individual can and will be overcome just as surely, but only by a return to fundamental moral and economic principles. Then we shall have more national self respect; more general respect for our Constitution and for the freedom which it provides. Then we can more effectively oppose the evil forces of socialism in its several forms, whose false prophets have brought nations, small and large, to this present critical pass. Then can we successfully assist the forces of humanity and righteousness throughout the nations of the world to relieve misery and to regain their own self-respect and their respect for the dignity and liberty of their individual citizens.

122 S. Michigan Ave.

CLINICAL NOTES

ELECTROSTIMULATION IN RESPIRATORY EMERGENCY

REPORT OF A CASE

Guy Zimmerman Jr., M.D., Warren, Pa.

W. H., a 45 year old white housewife, was admitted for the second time to Warren State Hospital from a city 65 miles distant on June 26, 1950, at 3:45 p. m. On arrival at the hospital she was in a semistuporous state and could not give an intelligible response. The ambulance driver accompanying her likewise was unable to provide any specific information, except that during the trip she seemed to rest quietly and he had heard she had spent the previous night in jail. Data obtained from the patient's previous admission revealed that she was considered neurotic and that she had been alcoholic for 12 years. The first admission was precipitated by a bromide psychosis.

Physical examination revealed a poorly nourished, semiconscious, dehydrated female, who uttered incomprehensible phrases and responded to painful stimuli. Her respiratory rate was 25, temperature 99.6 F. (rectal), pulse rate 80 and blood pressure 110/70. There were numerous abrasions and contusions about the thighs, face and back. Loud rhonchi were heard over both lung bases posteriorly. Heart sounds were good. Neurological examination revealed no cranial nerve involvement. There was no evidence of head injury. Deep reflexes were depressed, but there were no pathological reflexes. Pupillary response was normal. Ophthalmoscopic examination disclosed no abnormalities. The urine was normal except for the albumin content (1+); red blood cells numbered 3,690,000 and white blood cells 10,350. The hemoglobin level was 10 Gm. (60 per cent). The differential count showed 88 per cent polymorphonuclear cells and 12 per cent lymphocytes; blood urea nitrogen was 4.4 mg., blood alcohol 48 mg. and blood bromide 500 mg. per 100 cc.

Continuous intravenous infusions of isotonic sodium chloride solution were started; the patient was given 7½ grains (0.50 Gm.) of caffeine sodium benzoate every four hours and 600,000 units of penicillin every six hours. Her general condition did not seem critical. The following morning, 16 hours after admission, her condition suddenly became worse. The temperature rose to 102

Resident physician, Warren State Hospital, Warren, Pa.

F. (rectal); the pulse became weak, with a rate of 120, and respirations extremely shallow, with a rate of 55. Mottled cyanosis appeared on the face and both upper and lower extremities. There was pronounced respiratory impairment. In the course of one hour she became progressively worse, and death appeared near.

In this situation, a low modulation, alternating electric current varying from 3 to 12 milliamperes was directed through the diencephalic area of the brain, for stimulation of the respiratory center. Dramatic improvement was almost immediately noted. Respirations became deep at 14 per minute. The current was applied for two and one-half minutes. Cyanosis disappeared; deep reflexes returned to normal. During the next 48 hours this procedure was repeated whenever the exigency of the situation demanded, a total of five treatments being administered. After the fifth treatment no further stimulation was needed. Subsequently a typical drug psychosis developed (visual hallucinations, disorientation, fearfulness). Twelve days after admission, the patient was out of bed, rational and completely recovered from her acute episode.

TECHNIQUE

In the above case a low modulation, 3 to 12 milliampere current was directed through the diencephalic area of the brain. The current was delivered by a Reiter electrostimulator (model CW-47). Handle type button electrodes, moistened with isotonic sodium chloride solution, were applied 1 inch (2.5 cm.) directly cephalad to the apex of each ear. The current was initiated at 12 milliamperes and the intensity gradually lowered until a maximum depth of respiratory excursion was obtained. In each treatment session the current was applied for two and one-half minutes, with alternatingly increasing and decreasing intensity during the treatment interval. The instant of greatest stimulating effect seemed to occur at a current varying from 8 to 12 milliamperes, but deep respiratory excursion developed only when the current intensity was decreased to 3 to 5 milliamperes. In other words, a combination of alternating low and high current intensity seemed to produce the optimum effect on respiration. No convulsions resulted from this technique. Two operators are necessary, one to apply and support the electrodes and one to manipulate the controls. It is advisable that additional attendants be present to keep the patient in proper alinement.

COMMENT

Hirschfeld [1] and others have pointed out that modifications of the above electrostimulating technique are useful in the treatment of certain types of schizophrenia and have shown promise in relieving anxiety. An interesting side light evolved from Hirschfeld's work, in that, by modifying his original technique, he achieved a specific antidote for counteracting respiratory depression of barbiturate intoxication.

In the case herein described, after the acute emergency had passed and when historical information became available, it was learned that this patient had consumed an undetermined but large quantity of triple bromides, plus a relatively smaller amount of barbiturates. Also, eight hours after the acute condition, x-ray of the chest confirmed clinical evidence of a beginning pneumonic process in the lower lobe of the right lung. Thus in this case my co-workers and I were confronted with respiratory depression due to drugs (bromides and barbiturates) on which was superimposed an acute infectious process. Although the specific manner in which electrostimulation affects the respiratory center is by no means clear, it was rapidly effective in relieving a dire emergency caused by a combination of factors.

ROENTGENOLOGIC APPARATUS ATTACHABLE TO THE BELL FRACTURE TABLE

Ray K. Runge,
B. R. Kirklin, M.D.
and
Ralph K. Ghormley, M.D., Rochester, Minn.

Roentgenographic examination of fractures in the operating room with roentgenologic apparatus separate from the fracture table, a method commonly employed, has usually been attended with more or less inconvenience, inaccuracy in duplicating angles of view in a series of roentgenograms, and, if open operation is being performed, hazard of breaking asepsis.

Heretofore, for example, at the Mayo Clinic, a patient having a fracture of the neck or upper portion of the femur was placed on a fracture table with his legs extended and abducted and his feet secured to the foot rests. Then a mobile roentgenographic unit, consisting of a transformer, control stand, and tube stand with tube, was wheeled up to that side of the table corresponding to the injured hip. The tube was centered vertically over the region of the fracture, a loaded cassette was slipped into a tunnel under the hip and a roentgenogram, giving an anteroposterior view, was made. Then the unit was removed to make room for the surgeon.

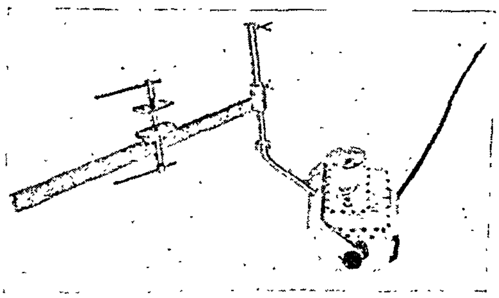

Fig. 1.—Unit 1, with angled post, bar, and clamp, detached from the table.

A second unit, identical with the first, was brought up to the foot of the table. The tube was placed between the patient's outstretched legs near the sound one and directed toward the region of the fracture so as to obtain a lateral view of the break, the cassette being held by an assistant against the patient's hip in a plane perpendicular to the axis of the rays.

Since another series of roentgenograms would be required at the end of the operation, and, perhaps, others

---

Helpful suggestions were received from all the consultants in the Section on Orthopedic Surgery during the development of this apparatus.

Technical Assistant (Mr. Runge); from the Section on Roentgenology (Dr. Kirklin) and the Section on Orthopedic Surgery (Dr. Ghormley), Mayo Clinic.

during its course, the second unit was left in place in the hope that the surgeon would not be obliged to move it or the table; additional roentgenograms should be made at the same angle as the first to assure valid comparisons. But often that hope was not realized; the table or tube was displaced, and the unit had to be reset, seldom in exactly the same place or in the same relation to the fracture. If replacement had to be done under a sterile sheet, it was difficult. The inevitable resetting of the first unit, the one used for the anteroposterior view, presented the same difficulties, and, when done during operation, risked contamination of the surgical field. Both units were heavy and occupied considerable floor space, so that they were hard to move about, and, wherever they were placed, they seemed to be in the way.

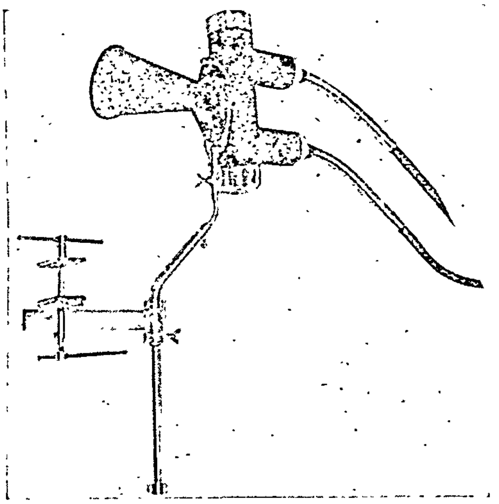

Fig. 2.—Unit 2, with angled post, bar, and clamp, detached from the table.

To obviate or, at least, to diminish these disadvantages and to facilitate the work, we have devised two tube assemblies that can be attached to the Bell table. New unit 1 consists of a standard transformer and small tube head compactly assembled (Fig. 1). It is suspended from the Bell table by an obliquely angled steel post, which is inserted into an eye in a relatively long arm, which, in turn, is inserted horizontally into a slot at the lower end of a bolt that holds together the halves of a steel clamp; this clamp rides between the two bars that constitute the central beam of the table. The clamp can be removed and placed elsewhere in the beam as desired. All connections are adjustable and can be locked by wing nuts or levers. This adjustability, together with the angulation of the supporting post, permits setting the unit at any position within a wide range. From the unit, a long, flexible cable, which carries primary current only, extends to a control-stand that operates both unit 1 and unit 2. As the new unit 1 is set immediately below the field of operation, it usually becomes soiled, so it is covered with plastic material that can be cleaned easily.

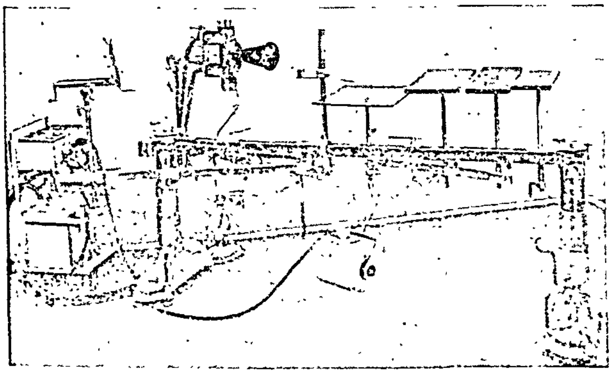

Fig. 3.—Bell table with both units attached to the table and connected with the mobile control-transformer stand.

Application of the new unit 1 differs from that of the old in that the new one is used to obtain a posteroanterior view of the fracture instead of the reverse. Accordingly, in the instance of a broken hip, the unit is set directly beneath the site of fracture, at the usual distance of 36 in. (91 cm.) from the cassette, which is laid on the patient's thigh, sterile towels or bags being used for protection as needed.

The new unit 2 consists of a small shockproof tube head with slightly modified cable connections (Fig. 2). Like unit 1, it is mounted on an obtusely angled post, and its connections with the table are the same as those of unit 1 except that the horizontal bar into which the post is inserted is short. All connections can be adjusted to suit, and locked. The tube is connected with the mobile control-transformer stand by long flexible cables that carry high-tension current only. With its many adjustable mountings, this unit, like its fellow, can be set in almost any position desired (Fig. 3).

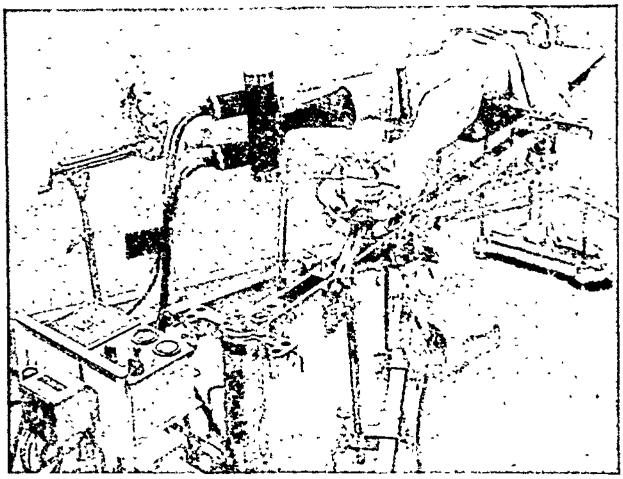

Fig. 4.—Apparatus attached to the Bell table; the patient is in position for posteroanterior and lateral roentgenography of the upper end of the femur.

In cases of fracture of the neck of the femur, for instance, unit 2 is set as close as possible to the internal aspect of the patient's sound leg, the small size of the new tube head giving it an advantage in this respect over the old (Fig. 4). The cone is directed toward the fracture for a lateral view, the cassette being held by an assistant against the hip and transversely to the axis of the rays at a target-film distance of 36 in. (91 cm.). The tube is left in place during the operation. It is so small that the surgeon is not likely to come into accidental contact with it or ask for its removal. If it does become necessary to remove the unit, the post can be inserted temporarily into one of the tubular front legs of the control stand.

Later, if further lateral views are required, the tube can be restored to its original position, and the angle of roentgenography will duplicate or closely approximate the original angle, because the patient, table, and roentgenologic unit will be in the same relation as before.

This assurance that successive views, both posteroanterior and lateral, will be made at or very near the same angle as the original, regardless of temporary changes of position, thus making comparisons reliable, is perhaps the most outstanding advantage of the new installation over the old. But there are other advantages, some of which have been mentioned in passing. Repetition of the posteroanterior view does not threaten contamination of the surgical field. The small size of unit 2 makes positioning for the lateral view easier and better. Both units, when set, are out of the way and are not likely to be pushed out of focus during operation. Since the units are attached to the table, the latter can be moved without disturbing relations. The units are much lighter than the old and can be removed, replaced, or shifted about with ease. When not in use, the control-transformer stand, with the posts of both tube units inserted into its tubular posts, occupies a floor space of only 15 in. by 16 in. (38 cm. by 40.6 cm.) so that the entire apparatus can be parked without taking up an undue amount of room (Fig. 5). The cost of the new units is comparable to that of the old.

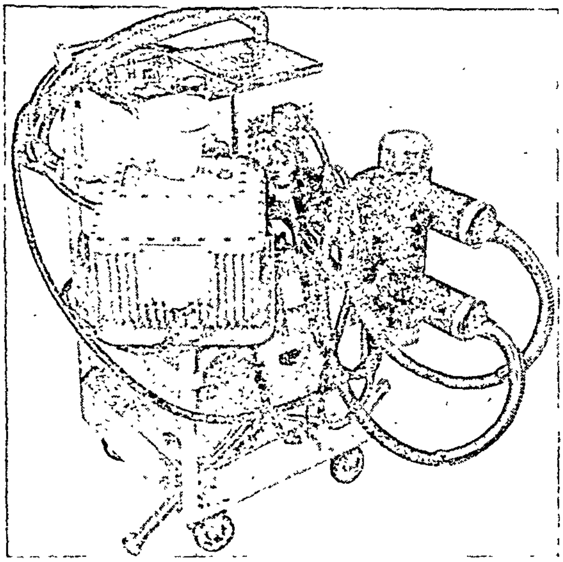

Fig. 5.—Both units mounted on the mobile control-transformer stand for storage.

Advances in Preventive Medicine.—During World War II, military preventive medicine reached a high state of development. This great conflict was the first one in history that was not followed by major epidemic diseases. In the Army alone, more than 10,000,000 men were mobilized to serve in some of the most unhealthful regions of the world, but their health was so well protected that the disease rates were lower than in any of our former wars. There were no serious epidemics, and the disease death rate was only 0.6 per thousand per year. This figure is low compared with the rate of almost 16 per thousand during World War I, and the still higher rate of 25 per thousand during the Spanish-American War.—James Stevens Simmons, M.D., *New England Journal of Medicine,* May 10, 1951.

COUNCIL ON FOODS AND NUTRITION

REPORT TO THE COUNCIL

The Council has authorized publication of the following report prepared by William B. Castle, C. A. Elvehjem, Charles D. May, Arnold D. Welch, Wolf W. Zuelzer, and Allan M. Butler. These men participated in the first of a series of conferences among active investigators on problems of infant nutrition held at the Massachusetts General Hospital on Nov. 16, 1950. Among the topics considered were (1) fundamental actions of vitamin B_{12} and folic acid, (2) distribution of these vitamins in foods, (3) the clinical evidence of deficiencies, and (4) the interrelations of vitamin B_{12}, folic acid, citrovorum factor, and ascorbic acid. JAMES R. WILSON, M.D., *Secretary.*

VITAMIN B_{12} AND FOLIC ACID IN INFANT NUTRITION

Perhaps the most important practical result of the deliberations of this conference was the emergence of a tentative attitude regarding the adequacy of vitamin B_{12} and folic acid in the milk diets customarily fed the growing infant from birth. Evidence was presented indicating that, after lactation is fully established, woman's milk contains between 0.1 and 1.0 microgram of vitamin B_{12} and folic acid per liter.[1] Cow's milk was reported to contain slightly more folic acid and definitely more vitamin B_{12} than human milk. Although there is some natural variation between samples, the conferees agreed that infants being fed artificially with cow's milk formulas would receive as much vitamin B_{12} and folic acid as the breast-fed infant, because these formulas usually contain 50 to 70% cow's milk. Thus, there would not seem to be any urgent need to supplement, with vitamin B_{12} or folic acid, the diet of normal infants being fed cow's milk.

The group attending this conference did not believe there was evidence of widespread deficiency of vitamin B_{12} and folic acid among infants and children as revealed by megaloblastic anemia or suboptimal growth. A cautious attitude was assumed toward employment of vitamin B_{12} or folic acid in an attempt to augment the normal growth of healthy infants being fed either artificially or by a well-nourished mother. Any studies claiming improved growth in normal children from supplementary vitamin B_{12} or folic acid will have to be appraised critically.

Certain pathologic conditions leading to reduced intake or impaired assimilation in infants might increase the need for these vitamins, but the therapeutic requirements of abnormal infants should not be confused with, or extended to, the requirements of normal infants. One of the conferees aptly expressed this distinction by stating that deficiency of vitamin B_{12} or folic acid was more likely to result from abnormalities within the individual child than from inadequate intake, because a proper diet, as now conceived, would provide amounts of vitamin B_{12} and folic acid which we have no reason to consider inadequate. The group did not feel that evidence presented justified widespread prophylactic use of vitamin B_{12} or folic acid in order to meet the extra requirements of the occasional pathologic situation.

The interdependence of requirements of vitamins was exemplified by the role of ascorbic acid in the requirement of folic acid. When adequate ascorbic acid is available, the normal infant's need for folic acid appears to be satisfied by the small amounts normally present in milk. If there is a deficiency of ascorbic acid, the amount of folic acid required to prevent megaloblastic anemia is considerably increased.

Carefully controlled studies of growth as well as the incidence of megaloblastosis would be helpful in detection of the circumstances that may lead to a deficiency of vitamin B_{12} or folic acid. Other indexes are also needed. Further studies of the role of the intestinal flora in the requirements, provision, and metabolism of vitamin B_{12} and folic acid would be beneficial. The role of gastric factor in the absorption of vitamin B_{12} in infancy must be determined before the adequacy of the intake of vitamin B_{12} can be evaluated from the content of the diet alone. The discussion of the fundamental metabolism of vitamin B_{12} and folic acid indicates that a final attitude toward the requirements of these vitamins in the diet will have to await a more complete understanding of their relationship. Folic acid appears to serve as a precursor of a biologically more active form (citrovorum factor or folinic acid). Ascorbic acid enhances the production of this factor from folic acid. The evidence does not indicate that vitamin B_{12} is critically involved in the conversion of folic acid to citrovorum factor, but it could be concerned with the subsequent formation, from this factor, of another metabolically significant compound.

---

[1] The mean figure used was 0.41 microgram for vitamin B_{12} and 0.71 microgram for folic acid.

A valid reason probably will be found for the natural provision of these potent vitamins in small amounts and in the ratio in which they occur in milks. Then we may be rewarded for a conservative approach and the avoidance of promiscuous use of these vitamins which play such a vital role in basic cellular growth and metabolism.

ACCEPTED FOODS

The following products have been accepted as conforming to the rules of the Council.

JAMES R. WILSON, M.D., *Secretary.*

Armour and Company, Chicago, Distributed by Gerber Products Company, Fremont, Mich.

GERBER-ARMOUR STRAINED BEEF HEARTS is made from meats (trimmed of fat, sinews and connective sheaths) with added salt, prepared under inspection of the Meat Inspection Division of the United States Department of Agriculture.

Analysis (submitted by manufacturer).—Total solids 18.7%, moisture 81.3%, ash 1.2%, fat 4.0%, protein (N × 6.25) 14.0%, carbohydrates (none).

Vitamins and Minerals	Mg./100 Gm.
Thiamine	0.041
Riboflavin	0.710
Nicotinic acid	4.35
Calcium	6.0
Phosphorus	121
Iron	3.0

Calories.—0.92 per gram; 26.1 per ounce.

Use.—For use in the feeding of infants, convalescents and others requiring a soft diet.

GERBER-ARMOUR STRAINED PORK is made from meats (trimmed of fat, sinews and connective sheaths) with added salt, prepared under inspection of the Meat Inspection Division of the United States Department of Agriculture.

Analysis (submitted by manufacturer).—Total solids 21.3%, moisture 78.7%, ash 1.1%, fat 5.1%, protein (N × 6.25) 14.6%, carbohydrates (none).

Vitamins and Minerals	Mg./100 Gm.
Thiamine	0.23
Riboflavin	0.21
Nicotinic acid	3.0
Calcium	8.0
Phosphorus	116
Iron	1.0

Calories.—1.04 per gram; 29.5 per ounce.

Use.—For use in the feeding of infants, convalescents and others requiring a soft diet.

The Borden Company, New York.

BIOLAC-MODIFIED POWDERED MILK. Ingredients: Whole milk, skim milk, milk sugar, concentrates from cod liver and fish liver oils (containing natural vitamin A), vitamin D, thiamine hydrochloride U. S. P., and ferric citrate U. S. P.

Analysis (submitted by manufacturer).—Total solids 98.0%, moisture 2.0%, minerals 4.3%, fat 20.2.%, protein 20.2%, lactose 53.3%.

Vitamins and Minerals	Per 100 Gm.	
Vitamin A	1,800	U.S.P. units
Vitamin D	290	U.S.P. units
Thiamine	0.18	mg.
Riboflavin	1.4	mg.
Calcium	610	mg.
Phosphorus	500	mg.
Iron	6	mg.

Calories.—4.8 per gram; 136 per av. oz.; 39.0 level tablespoon.

Use.—For use in infant feeding.

BREMIL POWDERED INFANT FOOD. Ingredients: Skim milk, lactose, palm oil, cocoanut oil, peanut oil, lecithin, calcium chloride, methionine D-L, ferrous sulfate, ascorbic acid, nicotinic acid, thiamine hydrochloride, riboflavin, vitamin A, vitamin D and potassium hydroxide.

Analysis (submitted by manufacturer).—Total solids 97.7%, moisture 2.3%, ash (minerals) 3.9%, fat 27.5%, protein 11.7%, carbohydrate 54.6%.

Vitamins and Minerals	Per 100 Gm.	
Vitamin A	2,570	U.S.P. units
Vitamin D	643	U.S.P. units
Thiamine	0.3	mg.
Riboflavin	0.8	mg.
Nicotinic acid	4.8	mg.
Ascorbic acid	24.0	mg.
Iron	6.4	mg.

Calories.—5.1 per gram; 144.6 per ounce; 44 per level tablespoon.

Use.—For use in infant feeding.

The H. J. Heinz Company, Pittsburgh.

HEINZ JUNIOR CHICKEN SOUP. Ingredients: Dressed chickens, rice, whole milk powder, flour, carrots, 50% cream, celery, onions, dried yeast, monosodium glutamate and salt in sufficient water to prepare properly.

Analysis (submitted by manufacturer).—Total solids 11.72%, moisture 88.28%, ash 1.03%, fat (by acid hydrolysis) 2.25%, protein (N × 6.25) 1.94%, crude fiber 0.06%, carbohydrates other than crude fiber (by difference) 6.40%, total sugar as sucrose 0.70%.

Vitamins and Minerals	Mg./100 Gm.
Thiamine	0.074
Riboflavin	0.100
Nicotinic acid	0.81
Calcium	31.0
Phosphorus	23.0
Iron	0.13
Copper	0.11

Calories.—0.55 per gram; 15.2 per ounce.

Use.—For use in the feeding of older infants and young children.

HEINZ JUNIOR MACARONI, TOMATOES, BEEF AND BACON. Ingredients: Macaroni, beef chuck, flour, 50% cream, carrots, sugar, tomato solids, bacon, dried yeast, whole milk powder, celery, onions, beef extract and salt in sufficient water necessary for preparation.

Analysis (submitted by manufacturer).—Total solids 16.49%, moisture 83.51%, ash 1.50%, fat (acid hydrolysis) 2.32%, protein (N × 6.25) 2.76%, crude fiber 0.19%, carbohydrates other than crude fiber (by difference) 9.72%, total sugar as sucrose 2.61%.

Vitamins and Minerals	Per 100 Gm.	
Vitamin A activity	470	I.U.
Thiamine	0.331	mg.
Riboflavin	0.146	mg.
Ascorbic acid	1.32	mg.
Nicotinic acid	1.41	mg.
Calcium	19.0	mg.
Phosphorus	25.0	mg.
Iron	0.68	mg.
Copper	0.3	mg.

Calories.—0.71 per gram; 20 per ounce.

Use.—For use in the feeding of older infants and young children.

Mead Johnson and Company, Evansville, Ind.

PABLUM BARLEY CEREAL. Ingredients: Barley flour, powdered beef bone, sodium chloride, dried yeast and iron.

Analysis (submitted by manufacturer).—Total solids 93.0%, moisture 7.0%, ash 4.4%, fat (ether extract) 0.3%, protein (N × 6.25) 10.5% crude fiber 0.7%, carbohydrates (other than crude fiber by difference) 77.1%.

Vitamins and Minerals	Mg./100 Gm.
Thiamine	1.06
Riboflavin	0.35
Calcium	770
Phosphorus	650
Iron	30
Copper	1

Calories.—3.5 per gram; 100 per ounce.

Use.—For use in the feeding of infants and young children, and for convalescents requiring a soft diet.

PABLUM RICE CEREAL. Ingredients: Rice flour, powdered beef bone, sodium chloride, iron, thiamine hydrochloride, riboflavin and nicotinamide.

Analysis (submitted by manufacturer).—Total solids 92.0%, moisture 8.0%, ash 3.8%, fat (ether extract) 0.2%, protein (N × 6.25) 6.0%, crude fiber 0.3%, carbohydrates other than crude fiber (by difference) 81.7%.

Vitamins and Minerals	Mg./100 Gm.
Thiamine	1.41
Riboflavin	1.06
Nicotinic acid	14.1
Calcium	790.0
Phosphorus	530.0
Iron	30.0
Copper	0.6

Calories.—3.5 per gram; 100 per ounce.

Use.—For use in the feeding of infants and young children, for convalescents requiring a soft diet, and for diets in allergies.

THE BIOSYNTHESIS OF CITRIC ACID

During the past decade, citric acid, long known to be a constituent of many body tissues and fluids, has come into prominence in the medical sciences as an important member of a catalytic cycle involved in the final cellular oxidation of carbohydrates, proteins, and fats, which is frequently termed the "Kreb citric acid cycle." The need for information concerning the biosynthesis of citric acid has thus, in turn, become important. Considerable progress has been made recently in phases of this problem pertaining to precursors and enzymes.

One of the first investigations bearing on the precursors of citric acid was that of a Yale group,[1] who found that the intravenous administration of the sodium salts of either malic, fumaric, or succinic acids was followed by a pronounced increase in citric acid in the urine, indicating that these substances served as citrate precursors. The Yale workers suggested chemical steps whereby the synthesis of citric acid from the above acids could occur. The above results, together with others, were incorporated by Krebs [2] into the now well-known "citric acid cycle." Krebs postulated that malic acid was converted to oxalacetic acid by the loss of two hydrogen atoms and that this then combined with pyruvic acid to form a seven-carbon intermediate compound, which then was converted to citric acid. Subsequent work, however, indicated that a two-carbon fragment, probably acetyl phosphate, combined with the oxalacetic acid directly to form citric acid. This has currently been verified with the use of oxalacetate labeled with radioactive carbon 14 [3] and by enzymatic studies with the use of acetate and oxalacetate.[4] The present concept that citric acid is synthesized from an acetyl group and oxalacetate is of considerable importance, since these two substances, in turn, arise from the metabolic breakdown of carbohydrates, fats, and proteins in the body. The concept of citric acid as a key intermediate in the "final common pathway" of catabolism is thus supported.

Other recent work has contributed to the elucidation of the enzymatic mechanism by which citric acid is synthesized in vivo. The results from several laboratories [5] have indicated that coenzyme A, formed from pantothenic acid, is involved in the biosynthesis of citric acid. Tissues from pantothenic-acid-deficient animals or yeast grown in a pantothenic-acid-deficient medium showed a decided reduction in ability to form citric acid from its precursors. Recently, the classical work of Ochoa and his group [6] at New York University has demonstrated the need of several other factors in the biosynthesis of citrate. One is a "condensing enzyme," which these investigators have isolated in crystalline form.[6a] Other factors concerned [6b] include magnesium ions, adenosine triphosphate, and, of course, the direct precursors, the acetyl group and oxalacetate, and coenzyme A.

These fundamental studies at once assume practical significance in this day of possible atomic warfare. A current report [7] indicates that there is a decided inhibition of citric acid synthesis in certain tissues of animals subjected to x-irradiation, presumably by way of the inactivation of the enzymatic mechanism of synthesis. This observation may well explain, in part at least, the damaging effects of certain types of radiations on tissues, inasmuch as the cells of these tissues are dependent for their viability on the energy released from the oxidation of metabolites by way of the citric acid cycle.

DIGITALIS AND POTASSIUM

A recent report by Lown, Salzberg, Enselberg, and Weston [1] throws further light on the long-recognized relation between potassium metabolism and the cardiac effects of digitalis. Ten patients in congestive heart failure served as subjects in this investigation. The threshold of mild toxicity to rapidly acting cardiac glycosides was determined during a control period and following procedures designed to induce a depletion of potassium. Criteria of toxicity were based on electrocardiographic findings of ventricular extrasystoles, impairment of auriculoventricular conduction, or alterations in the pacemaker. The gross potassium balance was determined by changes in urinary potassium excretion. One of four patients given mercurial diuretics after pretreatment with ammonium chloride showed an increased urinary potassium excretion and an increased sensitivity to acetyl strophanthidin, while two others showed no significant change in potassium excretion and no signs of digitalis poisoning. In the fourth patient, the threshold for ouabain toxicity after mercurial diuretics was greatly increased when potassium citrate was administered. Again, severe toxic symptoms followed therapy with mercurial diuretics in a patient on a constant maintenance dose of digoxin. Signs of toxicity did not develop, however, if potassium citrate was administered on days when the diuretic was given. Two patients depleted of potassium by vomiting,

diarrhea, and malnutrition appeared to be markedly sensitive to acetyl strophanthidin, though the serum potassium was significantly lowered in only one. In another patient, signs of digitalis toxicity could be abolished by oral potassium and reintroduced by mercurial diuresis. Nine days after the digitalis preparation was discontinued, mercurial diuretics failed to elicit digitalis toxicity. However, administration of insulin and glucose resulted in a decrease in serum potassium and the development of severe digitalis toxicity, which was abolished by potassium citrate. After the digitalis had been withheld for six weeks, glucose and insulin failed to induce signs of toxicity.

Since no significant changes in serum (or extracellular) potassium were observed in eight of the 10 patients, the authors concluded that the observed increased sensitivity to cardiac glycosides probably results from alterations in intracellular potassium distribution. That the effects are not due to simultaneous changes in distribution of water and electrolytes other than potassium is indicated by preliminary studies in which these variables were controlled. With the use of an artificial kidney, digitalis poisoning was induced by selective removal of potassium and abolished by restoration of the removed potassium. The results reported by Lown and his associates not only indicate that depletion of potassium increases the sensitivity of the heart to digitalis but suggest that the clinically observed increased sensitivity to digitalis in such conditions as acute myocardial infarction, pulmonary embolism, and acute infections may be due to the negative potassium balance which is a part of the bodily response to acute stress.

SYPHILIS CONTROL

The statement is heard with increasing frequency that syphilis is a vanishing disease. Many feel that penicillin therapy plus a continued nationwide program of case finding and education will soon relegate syphilis to the minor status of smallpox, typhoid and diphtheria. Others adopt a more conservative attitude. In a penetrating analysis, Moore [1] points out that the long term trends in the incidence of syphilis have not been altered dramatically by antibiotic therapy and that the ultimate goal of eradication may be more distant than the optimistic would have us believe.

Available data indicate that there has been a steady decrease in the incidence of syphilis in Europe and the United States for almost a century and that this decline has been interrupted only by temporary increases in morbidity during wars or periods of civil unrest. Two observations provide clues as to the mechanism of this decline: 1. It began long before the discovery of specific therapy for syphilis or the institution of public health measures for its control. 2. It has been accompanied by a progressive decrease in the acuteness of the disease, so that an infection that was often rapidly fatal in the 15th century has evolved into one of great chronicity. These observations suggest that a gradual process of adaptation has led to a decrease in the virulence of the parasite or an increase in the resistance of the host. In addition, there is evidence that the progressive improvement in socioeconomic conditions in Western civilization has contributed to the reduction in the incidence of syphilis. Whatever the mechanisms responsible for the decrease in morbidity before the days of specific therapy, it may be assumed that they are still operative and that they may be at least partially responsible for the continued decline.

Since the introduction of specific arsenical therapy in 1910, the rate of decline seems to have been accelerated somewhat. It is difficult to make precise statements because of the incompleteness of the available data and the tendency of the periodic fluctuations in the incidence of syphilis to obscure the long-range trends. It is even more difficult to evaluate the effect of a relatively new drug such as penicillin on the curve of incidence, since the total duration of penicillin therapy has not yet exceeded one of the naturally recurring cycles of increase and decrease in the incidence of the disease. It is tempting to attribute the sharp decrease in the attack rate in the past three or four years to the widespread use of penicillin, but the fact cannot be ignored that a decline at exactly the same rate occurred after World War I, before the discovery of penicillin. At least another decade of experience with penicillin will be required before its effect on the incidence of syphilis can be measured accurately. Its value in the control of the individual case of syphilis remains unchallenged, however. It is to date the drug of choice in this disease—effective, rapidly acting, nontoxic, and inexpensive.

A factor of equal or greater importance in the accelerated decline in the incidence of syphilis has been the application of modern public health measures to the control of venereal disease. Public health authorities in this country and in Europe have accomplished a prodigious task in finding and treating millions of infected persons and in educating the public. Their efforts are reflected in the continuing decrease in the infant and adult morbidity and mortality from syphilis.

According to Moore, however, the present rate of decline is not yet sufficiently significant (except possibly in Scandinavia) to promise eventual complete control in any country, to permit a relaxation of control efforts or to set a time limit on the achievement of the desired goal. In this country in 1949, there were still an estimated 3,000,000 persons with serologic evidence of infection with syphilis,[2] and an additional 150,000 persons acquired the infection in that year. Fourteen thousand syphilitic infants were born and 13,000 persons died of syphilis in the same year. Six thousand persons were sent to mental institutions because of syphilis. These figures continue to decrease, but past experience has shown that eradication of a disease in one country is not enough. The continual population exchanges permitted by modern transportation make new epidemics possible as long as an endemic focus remains anywhere in the world. Densely populated China and India have a high incidence

of syphilis, and these countries constitute a potential public health danger.

Moreover, as Moore points out, no infectious disease in the history of medicine has been eradicated or even partially controlled by the sole process of treatment of infected persons. Immunization may be the ultimate goal of public health control, but this in turn awaits further research on the problem of cultivation of the Treponema pallidum. Both public and private laboratories are doing their utmost to solve this problem, but financial support is needed. In the long run this type of approach is the most economical one, because global control by present methods is a practical impossibility.

MUSCULAR CONTRACTION

Muscle tissue accounts for about 40% of the mass of the body; it is obvious, therefore, that the pattern of metabolism of muscle dominates that of the body as a whole. The characteristic chemical reaction of the muscle—oxidation with the production of heat—is looked on as typical of that of the body as a whole. Of the muscle mass, about 80% of the solids is accounted for by proteins, which have long been looked on as possessing unique properties, both chemical and physical. The transformation of energy which is evolved in the course of glycolysis in muscle to mechanical work produced by the muscle is a phenomenon that is yet only partly understood. However, recent studies of muscle proteins themselves, along with the adaptation of new physical techniques, have greatly facilitated a better understanding of the intricate physical chemistry of muscular contraction.

An early suggestion of the unusual properties of muscle protein arose from the observation of Engelhardt and Ljubimowa,[1] who reported that the globulin of muscle could release phosphoric acid from adenosinetriphosphate. In other words, the protein fraction soluble in salt solution (myosin) exhibited enzymatic activity and this activity could not be separated from the protein itself. This observation has been confirmed by many investigators, although it has been held[2] that the enzymatic activity can be separated from the muscle globulin and, also, that there are other adenosinetriphosphatases than myosin.[3] The significance of the enzymatic degradation of adenosinetriphosphate by muscle protein is that the release of a relatively large amount of energy is thereby brought about; this chemical energy is involved in the contraction of the muscle.

The beginning of the newer concept of the functional activity of muscle proteins was discovery[4] that a constituent of the muscle stroma (actin) combines with the globulin myosin to form the protein complex known as actomyosin and that it is this complex that is the contractile unit in muscle tissue. The actin itself as well as the actomyosin complex can exist in molecules of globular form and also of fibrous form, and it appears that inorganic salts are required to promote the change of globular actomyosin to the fibrous form and that adenosinetriphosphate, likewise, is necessary for this transformation.[5] With the use of the electron microscope, F-actin was observed to form from G-actin; these fibers were long and 100 A thick and show conspicuous cross striations,[6] which fact may account for the changes in flow birefringence early seen when myosin reacts with adenosinetriphosphate.[7]

On the basis of the data currently available, it appears that the relaxed muscle is rich in energy and that G-actin and the complex of myosin and adenosinetriphosphate coexist in the dissociated form; on stimulation and in the presence of magnesium and potassium ions (among others) and of adenosinetriphosphate, G-actomyosin is formed which is still enzymatically inactive. There is a rapid change from G-actomyosin-adenosinetriphosphate to F-actomyosin-adenosinetriphosphate in the presence of salts and with the evolution of energy; the F-actomyosin is contractile in this energy-poor state and becomes enzymatically active, yielding energy which is absorbed by the system in reestablishing the high energy level of the relaxed muscle in which G-actin and myosin-adenosinetriphosphate are again separated. In this scheme, the energy appears to be used in the reestablishment of the energy-rich relaxed muscle, not for the contraction of the fibers of actomyosin. The need for further clarification of the intimate details of the process is apparent; with such conditions as myasthenia gravis and other muscular dystrophies in mind, it is plain that the rewards of a better understanding of muscular contraction will be enormous.

OPIATES AND PANCREATIC ENZYMES

Elevated levels of serum amylase and lipase are generally regarded as reliable evidence of pancreatic disease. Recent work, however, has demonstrated that the serum concentration of these enzymes may rise following the administration of opiates in the absence of pancreatic disease. In the course of studies on pancreatic function, Burke and co-workers[1] observed an increase in serum amylase in three patients without evidence of pancreatic disease following the subcutaneous injection of 16 mg. of morphine sulfate. At about the same time Gross and associates[2] observed elevated serum amylase and lipase levels following opiate administration in a patient whose pancreas appeared normal at the time of exploratory laparotomy. Suspecting that the opiate was responsible, they gave the patient 0.13 gm. of codeine sulfate hypodermically on two subsequent occasions and each time observed a pronounced rise after the injection. The amylase levels remained elevated for 24 hours. Extending their studies, they obtained similar results in five additional patients with biliary dyskinesia, but without evidence of pancreatic disease, and in one patient with penetrating duodenal ulcer. Twenty-one other patients with various diseases of the liver, gallbladder, stomach, and pancreas did not show this phenomenon.

The mechanism of this reaction is not entirely clear, but presumably morphine and its derivatives induce a spasm of the sphincter of Oddi, which in certain individuals who are anatomically [1] or allergically [2] predisposed results in an increase in pancreatic intraductal pressure and a reflux of enzymes into the blood stream. Regardless of the mechanism, it is apparent that this reaction, when it occurs, is a potential source of error in the clinical interpretation of elevated serum enzyme values. Often patients who are suspected of having pancreatitis are given morphine or codeine before blood is obtained for enzyme determination. In such circumstances, it is well to keep in mind that the serum enzyme levels may be altered by the opiates.

ULTRASONICS IN DIAGNOSIS

Because of their ability to penetrate tissues, high frequency acoustic vibrations have found both diagnostic and therapeutic applications in medicine. Until recently the therapeutic applications have received major emphasis. The thermal, mechanical, and chemical changes produced by ultrasonic vibrations as they pass through tissues have been utilized in the treatment of a great variety of diseases,[1] chiefly in Europe. Good results have been reported, but unfortunately most of the therapeutic evaluations have been based on clinical impressions alone and few controlled observations have been made. As a result, very little accurate scientific information on the therapeutic effectiveness of ultrasound has been obtained. The current studies of Nelson and co-workers [2] offer promise of correcting this situation.

In the last few years, increasing attention has been focused on the use of ultrasound in diagnosis. It has been found that alterations in the density or elasticity of a tissue can be detected with the aid of ultrasonic waves. Two approaches are available. In one, the tissue is exposed to the waves and the ultrasonic echoes returning to the surface are studied; in the other, the ultrasonic energy passing through the tissue is measured. The first method is an adaptation of a technique used for years in industry for the detection of flaws in metal castings and in navigation for depth sounding. It is based on the principle that ultrasonic waves passing through a medium are reflected back to the source as echoes when they encounter a surface (interface) of changing density within the medium. Thus, when the waves strike a tumor, a foreign body, or a collection of fluid within a tissue, some of them are reflected back to the surface as echoes. The intensity and character of the echoes give clues as to the consistency of the lesion, and the time required for the echoes to return to the surface gives an indication of the depth of the lesion. Using this technique, Ludwig and Struthers [3] have been able to detect gallstones and foreign bodies in animal tissues, and more recently French, Wild, and Neal [4] have reported the accurate localization of intracerebral neoplasms in a human brain removed immediately after death. Wild and Neal [5] have also reported distinguishing between carcinomatous and noncarcinomatous tumors of the breast by this method in two patients. The ultrasonic vibrations employed in the last two experiments were generated, transmitted, and received by a small instrument (ultrasonoscope), no larger than the bell of a stethoscope, that could easily be applied to any part of the body surface. Such an ultrasonoscope consists of a small metal chamber containing a piezoelectric crystal capable of converting high frequency electrical impulses into high frequency (15,000,000 cycles per second) mechanical vibrations. This crystal, activated intermittently by an electronic oscillator, sends pulses of ultrasonic energy into the tissues and receives the returning echoes during its quiescent period. These are reconverted by the crystal to electrical impulses that are recorded by a synchroscope. The final tracing appears as a series of waves resembling an electrocardiogram.

In the second diagnostic technique mentioned, separate transmitting and receiving crystals are placed on opposite sides of the tissue to be examined and the relative transmission of ultrasonic vibrations by different areas of tissue is measured. Since this transmission depends on the density, elasticity, homogeneity, and viscosity of the medium, variations in transmission indicate variations in texture of the tissue. By this method, Dussik [6] and Ballantine and associates [7] have obtained ultrasonic ventriculograms without air injection in living subjects and Denier [8] has detected intracranial foreign bodies in animals. In both the echo technique and the selective transmission method, ultrasonic vibrations of such short duration and low intensity are used that no symptoms are produced and no tissue alterations are detectable.[9] While both diagnostic methods are still capable of technical refinement, the results already obtained are definitely encouraging. These are fascinating developments that will bear watching.

ORGANIZATION SECTION

THE SCIENTIFIC EXHIBIT, LOS ANGELES CLINICAL SESSION

The Clinical Session of the American Medical Association will be held in Los Angeles, Dec. 4 to 7, 1951, at which time the Scientific Exhibit will again be one of the outstanding features. It is planned to have the Scientific Exhibit located on the balcony floor of the Shrine Convention Hall, easily reached by stairways from the Technical Exposition on the first floor and connecting with Al Malaikah Temple, in which will be located the lectures, clinical presentations, television, and motion pictures.

There will be special exhibits on fractures, on overweight, nutrition and health, and on noise in industry, presented by the various special exhibit committees. Groups of exhibits on cancer, diabetes, and heart disease will be well developed with the advice and cooperation of specialists in those subjects. Groups of exhibits on obstetrics and gynecology, pediatrics, internal medicine, surgery, dermatology, and miscellaneous subjects will be given prominent attention. While the interests of the specialist will not be overlooked, the main emphasis of the exhibit will be placed on the teaching value for the physician in general practice.

The Committee on Scientific Exhibit includes E. J. McCormick, M.D., Toledo, Ohio, Chairman; L. W. Larson, M.D., Bismarck, N. D., and Thomas P. Murdock, M.D., Meriden, Conn., with George F. Lull, M.D., Chicago; Ernest B. Howard, M.D., Chicago, and Austin Smith, M.D., Chicago, as ex officio members. Thomas G. Hull, Ph.D., Chicago, is Director of the Scientific Exhibit.

Application blanks for space are now available and may be obtained from the Director, Scientific Exhibit, American Medical Association, 535 N. Dearborn St., Chicago 10.

MEDICAL LEGISLATION

FEDERAL

National Advisory Committee for the Blind

Four identical bills have been introduced proposing to establish a National Advisory Committee for the Blind to study existing federal, state, and local activities related to the granting of service to the blind. The committee would be charged with making a report with recommendations to the President and Congress prior to Jan. 3, 1953, for accomplishing coordination of effort, attainment of maximum benefits for the blind, and such other matters as the committee deems appropriate. The committee would be composed of nine members to be appointed by the President, with not more than five members from the same political party. The committee would appoint a staff without regard to civil service laws. The bills would authorize the committee to hold hearings and to secure information from any executive department, bureau, or other government agency. Power to subpoena witnesses is included. The sum of $50,000 is proposed to finance the project. The four bills are S. 1714, by Senator Lehman of New York, for himself and three other senators; H. R. 4079, by Representative Boggs of Delaware; H. R. 4212, by Representative Priest of Tennessee, and H. R. 4605, by Representative Elliott of Alabama.

Hospital for Juvenile Drug Addicts

Four identical bills have been introduced in the House of Representatives which propose to establish a hospital for juvenile drug addicts. These bills would authorize the Federal Security Administrator to use any funds available for the remodeling of the Ellis Island Marine Hospital in New York for the purpose of making that hospital available for the treatment, under the supervision of the Surgeon General of the Public Health Service, of juvenile drug addicts. After the reopening of the hospital, the Surgeon General is further authorized to admit for care and treatment any juvenile drug addict on his own application or that of his parents or on the recommendation of state or city correctional officers. A juvenile drug addict is defined as any person under 21 who is known to use, other than under the immediate supervision and direction of a licensed physician, any narcotic drug or derivative thereof. These four identical bills are H. R. 4549, introduced by Representative Clemente of New York; H. R. 4569, by Representative Dollinger of New York; H. R. 4577, by Representative Fine of New York, and H. R. 4579, by Representative Klein of New York.

Antivivisection

Representative Baring of Nevada introduced H. R. 4519, which proposes to protect live dogs and cats against torture, brutality, and useless painful experimentation within the District of Columbia. This bill provides for fine and imprisonment for any person who experiments or operates in the District of Columbia on living dogs or cats for any purpose other than the healing, curing, or sterilization of such animals.

Problems of the Aging

Six identical house resolutions have been introduced which would authorize a select committee on problems of the aging to be composed of seven members of the House of Representatives, all appointed by the Speaker. This Select Committee would be charged with investigating the status of the older age group with respect to its manpower potential and the basic problems in the fields of employment, health, education, and community services in connection with the utilization of this group and the federal government's responsibility in the problem. The committee would report to the House, as soon as practicable during the present Congress, the results of its studies and recommendations. The usual authority is given to the committee to require by subpoena or otherwise, the attendance and testimony of witnesses and the production of books, records, and other material.

These six resolutions are all identical with H. RES. 238, reported previously. They are H. RES. 265, introduced by Representative Bolling of Missouri; H. RES. 266, by Representative Case of New Jersey; H. RES. 267, by Representative Heselton of Massachusetts; H. RES. 269, by Representative Price of Illinois; H. RES. 276, by Representative McKinnon of California, and H. RES. 284, by Representative Elliott of Alabama.

STATE

Illinois

Bills Introduced.—H. 1256 and S. 785 propose the establishment of a narcotics hospital in the City of Chicago. H. 1257 and S. 784 propose the establishment of three out-patient clinics in the City of Chicago for the treatment of narcotic addicts.

Massachusetts

Bills Introduced.—H. 2577 proposes to amend the narcotic law by making it unlawful to sell, furnish or give away narcotic drugs to a minor. H. 2585, Appendix D, proposes to authorize a special commission making an investigation and study relative to high blood pressure to print and sell its report. H. 2585, Appendix E, proposes to extend the existence of the special committee investigating the problem of high blood pressure.

Michigan

Bill Introduced.—S. C. R. 62 proposes the creation of a special committee to study problems pertaining to narcotics to determine whether or not present state laws are adequate.

Missouri

Bill Enacted.—S. 137 was approved June 25, 1951. It amends the workmen's compensation law by, among other things, providing that if an employee desires, he shall have the right to select his own physician, surgeon or other such person at his own expense.

The summary of federal legislation was prepared by the Washington Office of the American Medical Association and the summary of state legislation by the Bureau of Legal Medicine and Legislation.

PROCEEDINGS OF THE ATLANTIC CITY SESSION

THE SCIENTIFIC EXHIBIT

The Scientific Exhibit at the Atlantic City Session was one of the largest in the history of the American Medical Association and, in general quality of material shown and in teaching value, was also one of the best. The location in the Lower Level of Convention Hall seemed to meet with the approval of visitors, allowing for wider aisles, less crowding, and a general atmosphere of serious study. The advantages of the arrangements outweighed certain disadvantages. There were 297 exhibits occupying 306 booths.

The several special features attracted large and attentive audiences. The Special Exhibit on Fractures, an annual affair since 1926, and as popular as ever, occupied six booths, where demonstrations were carried on simultaneously and continuously under the guidance of Kellogg Speed, M.D., Chicago, assisted by Frederick A. Jostes, M.D., St. Louis, and Gordon M. Morrison, M.D., Boston, and a large group of demonstrators.

The exhibit symposium on Overweight, Nutrition, and Health occupied five booths, with an adjacent conference room seating 125 persons. Enthusiastic audiences overcrowded the available facilities most of the week. The committee in charge consisted of James R. Wilson, M.D., chairman, Chicago; Herbert H. Marks, New York, and Arnold B. Kurlander, M.D., Washington, D. C.

The special exhibit on fresh pathology was presented with the cooperation of the several medical schools and various hospitals in Philadelphia as well as the Atlantic City Hospital. The Section on Urology cooperated with the Section on Pathology and Physiology in presenting specimens. William P. Belk, M.D., Ernest E. Aegerter, M.D., Jefferson H. Clark, M.D., and Peter A. Herbut, M.D., were assisted by a large group of demonstrators.

Diabetes demonstrations were carried on in two booths and in an adjoining conference room under the guidance of Howard F. Root, M.D., Boston. Facilities were crowded to capacity at all times.

SECTION EXHIBITS

Groups of exhibits were presented by the various sections of the Scientific Assembly with the cooperation of the section representatives. The section representatives, together with the section secretaries, were more than usually active in seeking out new exhibits and in advice and assistance to the Committee on Scientific Exhibit. The result was 436 applications for space, besides numerous inquiries which were discouraged because there was no possibility of accommodating additional exhibits.

Anesthesiology.—There were 10 exhibits, of which one received a certificate of merit and one an honorable mention. The section representative was Scott M. Smith, M.D., Salt Lake City.

Dermatology and Syphilology.—The section had 13 exhibits. One received a certificate of merit and one an honorable mention. Exhibits on ionizing radiations was one of the features of this section. James A. Webster, M.D., Chicago, was the section representative.

Diseases of the Chest.—There were 12 exhibits in this group, with four awards, consisting of a gold medal, a certificate of merit, and two honorable mentions. The section representative was Edwin R. Levine, M.D., Chicago.

Experimental Medicine and Therapeutics.—In this group there were 15 exhibits, of which four received awards. There was a silver medal, a bronze medal, a certificate of merit, and an honorable mention. Robert W. Wilkins, M.D., Boston, was the section representative.

Gastro-Enterology and Proctology.—There were 12 exhibits in the group, of which two received awards, consisting of a certificate of merit and an honorable mention. The section representative for Gastro-Enterology was Everett D. Kiefer, M.D., Boston, and for Proctology, J. P. Nesselrod, M.D., Evanston, Ill.

General Practice.—This section had 11 exhibits with two awards, consisting of a certificate of merit and an honorable mention. Charles E. McArthur, M.D., Olympia, Wash., was the section representative.

Internal Medicine.—There were 18 exhibits in the group, with five awards, consisting of a certificate of merit and four honorable mentions. The section representative was Wesley W. Spink, M.D., Minneapolis.

Laryngology, Otology and Rhinology.—The section had 20 exhibits, of which four received awards, consisting of a certificate of merit and three honorable mentions. Members of the section cooperated in the group of exhibits on Noise in Industry. The section representative was Francis W. Davison, M.D., Danville, Pa.

Nervous and Mental Diseases.—There were 17 exhibits in the group, with three awards, consisting of a certificate of merit and two honorable mentions. Leon J. Whitsell, M.D., San Francisco, was the section representative.

Obstetrics and Gynecology.—The section had 12 exhibits, of which three received awards, consisting of a gold medal, a certificate of merit, and an honorable mention. Frederick H. Falls, M.D., Chicago, was the section representative.

Ophthalmology.—This section had nine exhibits, with four awards, consisting of a certificate of merit and three honorable mentions. The section exhibit committee was composed of Georgiana D. Theobald, M.D., Oak Park, Ill., chairman; Donald J. Lyle, M.D., Cincinnati, and Phillips Thygeson, M.D., San Jose, Calif.

Orthopedic Surgery.—There were 15 exhibits in the group, of which three received awards, consisting of one certificate of merit and two honorable mentions. Robert J. Joplin, M.D., Boston, was the section representative.

Pathology and Physiology.—This section had 20 exhibits, of which four received awards, consisting of one certificate of merit and three honorable mentions. Members of the section cooperated in the Special Exhibit on Fresh Pathology. Frank W. Konzelmann, M.D., Washington, D. C., served as the section representative.

Pediatrics.—There were 22 exhibits in the section, of which four received awards, consisting of one gold medal, one certificate of merit, and two honorable mentions. The section representative was F. Thomas Mitchell, M.D., Memphis, Tenn.

Physical Medicine and Rehabilitation.—There were nine exhibits in this section, of which three received awards, including one certificate of merit and two honorable mentions. Arthur L. Watkins, M.D., Boston, served as representative to the section.

Preventive and Industrial Medicine and Public Health.—There were 13 exhibits in the section, of which four received awards, consisting of one certificate of merit and three honorable mentions. A special feature was the group of exhibits on Noise in Industry sponsored by the Council on Industrial Health and the Council on Physical Medicine and Rehabilitation of the American Medical Association, together with the Committee on Conservation of Hearing of the American Academy of Ophthalmology and Otolaryngology, and the Acoustical Society of America. Paul A. Davis, M.D., Akron, Ohio, was the section representative.

Radiology.—There were 15 exhibits in the section, of which four received awards, including one certificate of merit and three honorable mentions. Richard H. Chamberlain, M.D., Philadelphia, was the section representative.

Surgery, General and Abdominal.—There were 27 exhibits in this section, of which five received awards, consisting of one silver medal, one bronze medal, one certificate of merit, and two honorable mentions. Walter G. Maddock, M.D., Chicago, was the section representative.

Urology.—This section had nine exhibits, of which two received awards, consisting of one certificate of merit and one honorable mention. The section participated in the Special Exhibit on Fresh Pathology with urologic specimens each afternoon. Another feature was a daily discussion of all exhibits in the Urology Section. The section exhibit committee consisted of Roger W. Barnes, M.D., Los Angeles, chairman; Rubin H. Flocks, M.D., Iowa City, and George H. Ewell, M.D., Madison, Wis.

There were nine miscellaneous exhibits, of which two received awards, consisting of one certificate of merit and one honorable mention.

MOTION PICTURES

Motion pictures were shown in two rooms on the Main Floor adjacent to the Technical Exposition. Thirty-seven films were presented once each day during the week, with the authors of 11 of the films being present to discuss them. The films were selected after careful previewing by competent authorities from more than 100 applications. The program was carried on with the cooperation of the Committee on Medical Motion Pictures.

AWARDS

Medal awards were made to exhibits for original investigation and for teaching value. Certificates of Merit and Honorable Mention awards were presented to the best exhibits in each section. The members of the Committee on Awards worked long and faithfully and were assisted by section representatives and other specialists called in for advice and consultation.

REPORT OF COMMITTEE ON AWARDS

The Committee on Awards made the following report:

MEDAL AWARDS

Group I.—Awards in this group are made for exhibits of individual investigations, which are judged on the basis of originality and excellence of presentation. Duplicate Gold Medals are awarded in Group I.

The GOLD MEDAL to Robert P. Glover, Charles P. Bailey, and Thomas J. E. O'Neill, Hahnemann Medical College and Hospital, Episcopal Hospital, Philadelphia, for the exhibit on Intracardiac Surgery for Acquired and Congenital Heart Disease.

The GOLD MEDAL to Willis J. Potts, William L. Riker, and Robert DeBord, Children's Memorial Hospital, Chicago, for the exhibit on Surgery for Congenital Heart Disease.

The SILVER MEDAL to David Cayer and W. E. Cornatzer, Bowman Gray School of Medicine, Winston-Salem, N. C., for the exhibit on Role of Lipotropic Agents in Liver Disease—A Study of Phospholipide Synthesis Using Radiophosphorus.

The BRONZE MEDAL to William P. Boger, Walter V. Matteucci, Nelson H. Schimmel, and Harrison F. Flippin, Philadelphia General Hospital, Philadelphia, for the exhibit on Benemid—Its Influence on PAS, Penicillin, and Other Antibiotics.

Group II.—Awards in this group are made for exhibits which do not exemplify purely experimental studies but are judged on the basis of excellence of correlating facts and excellence of presentation.

The GOLD MEDAL to Walter W. Williams, Springfield Hospital, Springfield, Mass., and Irving F. Stein and Melvin R. Cohen, Michael Reese Hospital, Chicago, for the exhibit on Fertility and Sterility—Diagnostic and Prognostic Procedures.

The SILVER MEDAL to C. Stuart Welch and William Dameshek, Pratt Diagnostic Clinic, New England Center Hospital, Boston, for the exhibit on Surgery of the Spleen.

The BRONZE MEDAL to Robert R. Linton, Chester M. Jones, John J. Cranley Jr., James L. Buchanan, Daniel S. Ellis, and Arthur French, Brookline, Mass., for the exhibit on the Surgical Treatment of Bleeding Esophageal Varices (Portal Hypertension).

SECTION AWARDS

Certificates of Merit and Honorable Mention are awarded to the following in each Section.

Section on Anesthesiology.—Certificate of Merit to Lloyd D. Seager and Edwin L. Rushia, University of Arkansas School of Medicine, Little Rock, Ark., for the exhibit on Curare Antidotes—Anticurare Action of Some Neostigmine Derivatives.

Honorable Mention to John G. P. Cleland, University of Oregon Medical School and Oregon City Hospital, Oregon City, Ore., for the exhibit on Continuous Segmental Analgesia in Obstetrics and Surgery.

Section on Dermatology and Syphilology.—Certificate of Merit to Robert R. Kierland, P. A. O'Leary, L. A. Brunsting, and J. W. Didcoct, Mayo Clinic, Rochester, Minn., for the exhibit on Cortisone and ACTH—Their Use in Dermatology.

Honorable Mention to Eugene S. Bereston and Maurice Sullivan, Johns Hopkins Hospital, Baltimore, for the exhibit on Topical Therapy of *Tinea Capitis Due to M. Audouini.*

Section on Diseases of the Chest.—Certificate of Merit to Chevalier L. Jackson, John Franklin Huber, and Charles M. Norris, Temple University School of Medicine, Philadelphia, for the exhibit on the Segmental Bronchi and Bronchopulmonary Segments.

Honorable Mention to Hurley L. Motley, Burgess Gordon, Peter A. Theodos, and Joseph F. Tomashefski, The Barton Memorial Hospital, Philadelphia, for the exhibit on Studies of Pulmonary Function Impairment in Coal Miners.

Honorable Mention to Samuel H. Belgorod, New York, for the exhibit on Chemotherapy in Tuberculosis.

Section on Experimental Medicine and Therapeutics.—Certificate of Merit to J. L. Bollman, Mayo Clinic, Rochester, Minn., for the exhibit on Liver Lymph and Intestinal Lymph in Experimental Cirrhosis and Ascites.

Honorable Mention to Augustus Gibson, Charles E. Lyght, Stephen Fromer, and Lyon P. Strean, Merck & Company, Inc., Rahway, N. J., for the exhibit on Cortisone as an Investigative and Therapeutic Agent.

Section on Gastro-Enterology and Proctology.—Certificate of Merit to Asher Winkelstein, The Mount Sinai Hospital, New York, for the exhibit on Banthine for Peptic Ulcer—Clinical and Physiologic Studies.

Honorable Mention to Paul L. Shallenberger, Charles H. DeWan, Clayton B. Weed Jr., and John Reganis, Guthrie Clinic, Sayre, Pa., for the exhibit on Gastroscopic Biopsy.

Section on General Practice.—Certificate of Merit to Karl Haase, Veterans Administration Center, Los Angeles, and Bernard Daitz, Department of Medicine and Surgery, Veterans Administration, Washington, D. C., for the exhibit on Chronic Illness—A Growing Challenge.

Honorable Mention to Steven O. Schwartz and Sherman R. Kaplan, Hektoen Institute for Medical Research of the Cook County Hospital, Chicago, for the exhibit on Iron Deficiency Anemia—A Dynamic Concept.

Section on Internal Medicine.—Certificate of Merit to Charles P. Emerson Jr. and Franklin G. Ebaugh Jr., Boston University School of Medicine and Evans Memorial Hospital, Carl W. Walter, James L. Tullis, C. A. Janeway, L. K. Diamond, John G. Gibson II, Edward S. Buckley Jr., and Theodore Sack, Harvard Medical School, Peter Bent Brigham Hospital and Children's Hospital, Boston, for the exhibit on New Developments in Collection and Processing of Donor Blood.

Honorable Mention to Herbert C. Allen Jr., Raymond L. Libby, Benedict Cassen, and William E. Goodwin, Radioisotope Unit, Veterans Administration Center and University of California at Los Angeles School of Medicine, Los Angeles, for the exhibit on The Scintillation Counter—A New Diagnostic Instrument.

Honorable Mention to Arthur M. Master, Isaac Goldstein, and Max B. Walters, Mount Sinai Hospital, New York, for the exhibit on New Limits of Normal Blood Pressure—Clinical Application.

Honorable Mention to Ella Roberts, Marian Wikingsson, and C. Robert Wells, Philadelphia, for the exhibit on Ten Years' Experience with Sulfonamides in the Prophylaxis of Rheumatic Fever.

Honorable Mention to Kendall Emerson Jr., Stanley Kahn, John Vester, and Dexter Nelson, Peter Bent Brigham Hospital, Boston, for the exhibit on Cation Exchange Resins of the Carboxyl Type in the Treatment of Edema.

Section on Laryngology, Otology and Rhinology.—Certificate of Merit to Aram Glorig, Silver Spring, Md., for the exhibit on Dihydrostreptomycin and Streptomycin and the Inner Ear.

Honorable Mention to Lawrence Reynolds, K. E. Corrigan, H. S. Hayden, and F. R. Birkhill, Harper Hospital, Detroit, for the exhibit on Radioactive Isotope Tracers in Early Detection of Malignancy.

Honorable Mention to William C. Thornell, University of Cincinnati College of Medicine, Cincinnati, for the exhibit on A New Intralaryngeal Approach for Arytenoidectomy in Bilateral Abductor Vocal Cord Paralysis.

Honorable Mention to Irvin Hantman, Georgetown University School of Medicine and Episcopal Eye, Ear and Throat Hospital, Washington, D. C., for the exhibit on Diseases of the Ear Drum.

Section on Nervous and Mental Diseases.—Certificate of Merit to Ernest Spiegel, Henry T. Wycis, Herbert Freed, and H. Baird, Temple University School of Medicine and Hospital, Philadelphia, for the exhibit on The Stereoencephalotome and Its Application.

Honorable Mention to Ralph B. Cloward, Honolulu, Hawaii, for the exhibit on Treatment of Ruptured Lumbar Disks by Intervertebral Fusion, Surgical Techniques and Statistics.

Honorable Mention to George E. Moore, Douglas A. Kohl, Shelley N. Chou, and William T. Peyton, University of Minnesota Hospitals, Minneapolis, for the exhibit on Use of Fluorescein and Radioactive Isotopes in Localization of Brain Tumors.

Section on Obstetrics and Gynecology.—Certificate of Merit to H. E. Nieburgs and E. R. Pund, Medical College of Georgia, Augusta, Ga., for the exhibit on Etiologic and Diagnostic Factors in Cervical Cancer.

Honorable Mention to Mario A. Castallo, Amos S. Wainer, and John M. Stack, Jefferson Medical College and Hospital, Philadelphia, for the exhibit on Experimental Recanalization of Fallopian Tubes.

Section on Ophthalmology.—Certificate of Merit to D. M. Gordon, J. M. McLean, and H. Koteen, Cornell University Medical College, New York, for the exhibit on ACTH and Cortisone in Ophthalmology.

Honorable Mention to David D. Donaldson, Howe Laboratory, Boston, for the exhibit on Stereophotographs of Anatomical Preparations for Teaching Neuro-ophthalmology.

Honorable Mention to Arthur J. Bedell, Albany, N. Y., for the exhibit on The Macular Region in the Elderly.

Honorable Mention to Glen G. Gibson, Robert W. Mather and Robert H. Peckham, Temple University School of Medicine, Philadelphia, for the exhibit on Diagrammatic and Photographic Presentation of Retinal Arteriolar Changes in Hypertension.

Section on Orthopedic Surgery.—Certificate of Merit to G. W. Hyatt, T. C. Turner, and Andrew Bassett, United States Naval Medical School, Bethesda, Md., for the exhibit on New Methods of Preserving Skin, Bone, and Blood Vessels.

Honorable Mention to George G. Rowe and Maurice B. Roche, Washington University School of Medicine, St. Louis, for the exhibit on The Separate Neural Arch.

Honorable Mention to Frederick Lee Liebolt and Louise Beury Flynn, New York Hospital, Cornell Medical Center, New York, for the exhibit on Injuries to the Menisci of the Knee Joint.

Section on Pathology and Physiology.—Certificate of Merit to Karl Singer and Amoz I. Chernoff, Medical Research Institute, Michael Reese Hospital, Chicago, for the exhibit on Pathogenesis of Sickle Cell Anemia and Other Hereditary Hemolytic Syndromes.

Honorable Mention to Hans Elias and Hans Popper, Chicago Medical School and Hektoen Institute of Medical Research, Cook County Hospital, Chicago, for the exhibit on Functional Anatomy of the Normal and Cirrhotic Liver.

Honorable Mention to Shepard Shapiro, New York, for the exhibit on Oral Anticoagulant Therapy.

Honorable Mention to Albert E. Bothe and F. O. Zillessen, Jeanes Hospital, Philadelphia, and A. J. Dalton, National Cancer Institute, Bethesda, Md., for the exhibit on the Golgi Material and Mitochondria in Benign and Malignant Lesions.

Section on Pediatrics.—Certificate of Merit to Benjamin M. Gasul, Egbert H. Fell, Maurice Lev, William P. Mavrelis, Oldrich Prec, and Raul Casas, Hektoen Institute of Medical Research, Cook County Children's Hospital, Presbyterian Hospital, and the University of Illinois College of Medicine, Chicago, for the exhibit on Congenital Heart Disease in Pediatrics—A Study of Over 700 Cases.

Honorable Mention to Leon Unger, A. Alvin Wolf, Albert H. Unger, and Tybee Sue Meyers, Northwestern University Medical School, Chicago, for the exhibit on Bronchial Asthma in Children.

Honorable Mention to Jay M. Arena and Grant Taylor, Duke Hospital, Durham, N. C., for the exhibit on Accidental Poisoning in Children.

Section on Physical Medicine and Rehabilitation.—Certificate of Merit to F. A. Hellebrandt and Sara Jane Houtz, Medical College of Virginia, Richmond, Va., and National Society for Crippled Children and Adults, Inc., for the exhibit on Evaluating the Physical Disabilities of the Cerebral Palsied.

Honorable Mention to Archer S. Gordon, Max S. Sadove, Frank Raymon, and Andrew C. Ivy, University of Illinois College of Medicine, Chicago, for the exhibit on Artificial Respiration—Recent Advances in Manual Methods.

Honorable Mention to Julia F. Herrick, Frank H. Krusen, Gordon M. Martin, and Earl C. Elkins, Mayo Foundation, Rochester, Minn., for the exhibit on Effects of Ultrasonic Energy on Tissues.

Section on Preventive and Industrial Medicine and Public Health.—Certificate of Merit to Werner Henle and M. Michael Sigel, Children's Hospital of Philadelphia, and University of Pennsylvania School of Medicine, Philadelphia, for the exhibit on Virus Diagnostic Laboratory.

Honorable Mention to Thomas D. Dublin, National Health Council, New York, for the exhibit on Healthy Communities Don't Just Happen.

Honorable Mention to George N. Papanicolaou, J. E. Seybolt, W. A. Cooper, L. W. Hanlon, and Irene Koprowska, New York, for the exhibit on Cytology of Cancer.

Honorable Mention to Elmer H. Loughlin, Aurele A. Joseph, and Irving Rappaport with Hodelin René, Institute of Inter-American Affairs, Port-au-Prince, Haiti, on Yaws Control with Antibiotics.

Section on Radiology.—Certificate of Merit to Edwin C. Ernst, Barnard Free Skin and Cancer Hospital, St. Louis, for the exhibit on Recent New Developments in the Application of Radium in the Treatment of Carcinoma of the Cervix.

Honorable Mention to Roger A. Harvey, John S. Laughlin, and Lewis L. Haas, University of Illinois College of Medicine, Chicago, for the exhibit on Medical Application of the Betatron.

Honorable Mention to Wallace S. Tirman, Harry W. Banker, and Charles B. Caylor, Bluffton, Ind., for the exhibit on Microradiography.

Honorable Mention to Walter S. Lusby, John W. Coltman, Richard L. Longini, and Fitz-Hugh B. Marshall, Westinghouse Electric Corporation, Baltimore, for the exhibit on Fluoroscopic Image Amplification.

Section on Surgery, General and Abdominal.—Certificate of Merit to H. E. Bacon, L. E. McCrea, H. D. Trimpi, C. C. Jackson, and I. Sauer, *Temple University Hospital, Philadelphia,* for the exhibit on Extended Radical Resection for Cancer of the Rectum; Pelvic Viscerectomy with Cutaneous Ureterostomy.

Honorable Mention to Julian B. Herrmann, Montefiore Hospital, New York, for the exhibit on The Effect of Hormonal Imbalance on Advanced Mammary Carcinoma.

Honorable Mention to Richard B. Cattell and Kenneth W. Warren, The Lahey Clinic, Boston, for the exhibit on Surgical Diseases of the Pancreas.

Section on Urology.—Certificate of Merit to M. Leopold Brodny and Samuel A. Robins, Beth Israel Hospital, Tufts College Medical School, Boston, for the exhibit on Prostatography.

Honorable Mention to R. H. Flocks, R. G. Bunge, J. S. Greenleaf, W. N. Harness, J. M. Tudor, and L. J. Prendergast, University Hospital, Iowa City, for the exhibit on Carcinoma of the Prostate.

Section on Miscellaneous Topics.—Certificate of Merit to A. Reynolds Crane, 200th Anniversary Committee, Pennsylvania Hospital, Philadelphia, for the exhibit on Pennsylvania Hospital—200th Anniversary of the Nation's First Hospital.

Honorable Mention to Major General Harry G. Armstrong, USAF (MC) Surgeon General, Department of the Air Force, Washington, D. C., for the exhibit on The Emergency Medical Crash Services (Featuring the New Mobile Ward Crash Cart).

The Committee on Awards recommends that recognition be given to the following groups for their efforts in presenting valuable clinical demonstrations on (1) fractures, (2) overweight, nutrition, and health, (3) pathology, (4) diabetes, and (5) noise in industry: Exhibit Committee on Fractures, Dr. Kellogg Speed, Chicago, *Chairman;* Exhibit Committee on Overweight, Nutrition and Health, Dr. James R. Wilson, Chicago, Chairman; Exhibit Committee on Diabetes, Dr. Howard F. Root, Boston, Chairman; Exhibit Committee on Pathology Specimens, Dr. William P. Belk, Philadelphia, Chairman, and Council on Industrial Health and Council on Physical Medicine and Rehabilitation of the American Medical Association, Chicago, together with the Committee on Conservation of Hearing of the American Academy of Ophthalmology and Otolaryngology and the Acoustical Society of America.

The Committee on Awards was greatly impressed with the excellence of the motion picture program.

Respectfully submitted,

O. P. J. Falk, M.D., St. Louis, Mo., Chairman.
Keith S. Grimson, M.D., Durham, N. C.
Paul H. Holinger, M.D., Chicago.
Leonard A. Scheele, M.D., Washington, D. C.
W. Walter Wasson, M.D., Denver.

MINUTES OF THE SCIENTIFIC SECTIONS

SECTION ON ANESTHESIOLOGY

Wednesday, June 13—Morning

The meeting was called to order at 9 o'clock by the chairman, Dr. H. Boyd Stewart, Tulsa, Okla.

Drs. Robert D. Dripps and Leroy D. Vandam, Philadelphia, presented a paper on "The Hazards of Lumbar Puncture," which was discussed by Drs. Frank Cole, Lincoln, Neb., and Urban H. Eversole, Boston.

The following papers were read as a symposium on "Plasma Volume Expanders in the Treatment of Shock":

Dr. Jesse L. Bollman, Rochester, Minn.: "Volemic Substances for the Maintenance of Plasma Volume After Blood Loss."

Dr. Frank W. Hartman, Detroit: "Tissue Changes Following the Use of Plasma Substitutes."

Dr. Walter L. Bloom, Emory University, Ga.: "Present Status of Plasma Volume Expanders in the Treatment of Shock: Clinical Laboratory Studies."

Drs. Winchell McK. Craig, Howard K. Gray and John S. Lundy, Rochester, Minn.: "Present Status of Plasma Volume Expanders in the Treatment of Shock: Clinical Results in Surgery."

These four papers were discussed by Drs. I. S. Ravdin, Philadelphia; Edwin J. Pulaski, San Antonio, Texas; Donald E. Hale, Cleveland; Lloyd R. Newhouser, Washington, D. C.; Everett I. Evans, Richmond, Va.; Douglas B. Kendrick Jr., Washington, D. C.; Frederick M. Allen, New York, and John Scudder, New York.

Thursday, June 14—Morning

The following officers were elected: chairman, Dr. Stevens J. Martin, Hartford, Conn.; vice chairman, Dr. Mary M. Lyons, Ravinia, Ill., and representative to the Scientific Exhibit, Dr. Scott M. Smith, Salt Lake City. Drs. Stewart C. Cullen, Iowa City; Perry P. Volpitto, Augusta, Ga., and Stevens J. Martin, Hartford, Conn., were elected members of the American Board of Anesthesiology.

Dr. R. J. Whitacre, East Cleveland, Ohio, presented a report from the American Board of Anesthesiology.

Dr. Edward B. Tuohy, Washington, D. C., in the absence of the delegate, Dr. Ruth, gave a brief report of the activities being considered by the House of Delegates.

On motion of Dr. Moses H. Krakow, New York, seconded by Dr. Edward B. Tuohy, Washington, D. C., it was voted that the question of asking the American Medical Association to provide ballot forms for election of section officers be referred to the executive committee for decision and action.

Drs. F. Paul Ansbro, Francis S. Latteri and Benson Bodell, Brooklyn, presented a paper on "Continuous Lumbar Epidural Block: The Answer to Spinal Anesthesia Complications." This paper was discussed by Drs. Robert A. Hingson, Baltimore, and Edward B. Tuohy, Washington, D. C.

Dr. Carl S. Hellijas, Hartford, Conn., read a paper, "Preoperative and Postoperative Respiratory Studies," which was discussed by Drs. Irving M. Pallin and Barnett A. Greene, Brooklyn.

Dr. Roger W. Ridley, Rochester, Minn., read a paper, "Studies of the Minute Volume Respiration During Anesthesia," which was discussed by Dr. Edward T. Lawless, Bloomfield, N. J.

With the vice chairman, Dr. Stevens J. Martin, presiding, Dr. H. Boyd Stewart, Tulsa, Okla., read the chairman's address, "Professional Obligations."

Drs. A. S. Keats, G. L. D'Allessandro and Henry K. Beecher, Boston, presented a paper, "A Controlled Study of the Treatment of Pain by Intravenous Procaine." This was discussed by Drs. Leo V. Hand, Boston, Raphael W. Robertazzi, Brooklyn, Frederick M. Allen, New York, and James E. Eckenhoff, Philadelphia.

Drs. V. K. Stoelting and J. P. Graf, Indianapolis, presented a paper on "Intravenous Propyl-Methyl-Carbingl Allyl Barbituric Acid for Hypnosis During Nitrous Oxide Anesthesia." This paper was discussed by Drs. R. J. Whitacre, East Cleveland, Ohio, and James E. Eckenhoff, Philadelphia.

Resuming the chair, the chairman read a resolution proposed by Dr. Henry S. Ruth, Haverford, Pa., section delegate, suggesting that the executive committees of the scientific sections through the section secretaries, respectfully request the Board of Trustees to allocate additional funds to each section sufficient to pay the expenses, in full or in part, of the section delegates to the meetings of the American Medical Association House of Delegates. It was moved by Dr. R. J. Whitacre, East Cleveland, Ohio, that authority be delegated to the executive committee to amend the resolution to proper form for presentation to the House of Delegates. The motion was regularly seconded and carried.

It was regularly moved, seconded and carried that a vote of thanks be extended to Dr. Scott M. Smith, Salt Lake City, for his excellent work with the Scientific Exhibit.

The chairman announced that a certificate of merit had been presented to Drs. Lloyd D. Seager and Edwin L. Rushia, Little Rock, Ark., for their scientific exhibit, and that honorable mention had been given to Dr. John G. P. Cleland, Oregon City, Ore., for his exhibit.

The newly elected officers were introduced.

Friday, June 15—Morning

Joint Meeting with Section on Urology

The chairman of the Section on Urology, Dr. John Arthur Taylor, New York, read the chairman's address, "Prostatectomy in the Aged." The address was discussed by Drs. Moses H. Krakow, New York, Rubin Flocks, Iowa City, and Thomas D. Moore, Memphis, Tenn.

Drs. Stevens J. Martin and Thomas M. Feeney, Hartford, Conn., presented a paper, "Anesthesia in Pediatric Urology," which was discussed by Drs. Meredith F. Campbell, New York, and Margery Deming, Philadelphia.

Dr. Richard Chute, Boston, read a paper on "The Preoperative and Postoperative Management of Aged Patients Undergoing Urological Surgery with Particular Reference to Problems of Nutrition and Body Chemistry." This paper was discussed by Drs. C. Walter Metz, Denver; Elmer Belt, Los Angeles; Edward N. Cook, Rochester, Minn., and John Arthur Taylor, New York.

Drs. E. M. Papper and George F. Cahill, New York, presented a paper, "Anesthetic Problems in the Hormonal Disorders of the Adrenal Gland," which was discussed by Dr. Francis F. Foldes, Pittsburgh.

Dr. Elmer Hess, Erie, Pa., spoke briefly on the work of the American Medical Association.

Dr. Hugh J. Jewett, Baltimore, read a paper, "Infiltrating Carcinoma of the Bladder: Relation of Early Diagnosis to Five Year Survival Rate After Complete Extirpation." This paper was discussed by Drs. E. Joseph Delmonico, Syracuse, N. Y.; Edward N. Cook, Rochester, Minn., and Meyer M. Melicow, New York.

Drs. Lloyd H. Mousel and O. A. Nelson, Seattle, presented a paper, "Renal Tumors," which was discussed by Drs. Wyland F. Leadbetter, Boston; Henry S. Ruth, Haverford, Pa.; Richard Chute, Boston; Henry K. Sangree, Philadelphia, and Meyer M. Melicow, New York.

SECTION ON DERMATOLOGY AND SYPHILOLOGY

Wednesday, June 13—Afternoon

The meeting was called to order at 2:10 p. m. by the vice chairman, Dr. John Eric Dalton, Indianapolis.

Dr. Dalton gave a résumé of the career of the Chairman of the Section, Dr. Dudley C. Smith, who died shortly after his election in 1950.

Dr. James R. Webster, Chicago, read the report of the Committee on Scientific Exhibit and announced the awards for scientific exhibits.

In the absence of Dr. Clinton W. Lane, St. Louis, Dr. John G. Downing, Boston, was asked to serve as a member of the Executive Committee.

Dr. Anthony C. Cipollaro, New York, presented the report of the Nominating Committee.

Dr. John Eric Dalton, Indianapolis, read the chairman's address, "History, Problems and Costs of the Industrial Health Movement with Special Reference to the Dermatoses."

Drs. Robert R. Kierland, Paul A. O'Leary, Louis A. Brunsting and John W. Didcoct, Rochester, Minn., presented a paper on "The Use of Cortisone and ACTH in Dermatology."

Drs. Thomas H. Sternberg and Victor D. Newcomer, Los Angeles, presented a paper on "Treatment of Atopic Dermatitis with Cortisone."

These two papers were discussed by Drs. Ray O. Noojin, Birmingham, Ala.; Boynton H. Booth, Indianapolis; E. E. Barksdale, Washington, D. C.; Maurice J. Costello, New York; James R. Webster, Chicago; Robert R. Kierland, Rochester, Minn., and Thomas H. Sternberg, Los Angeles.

Dr. John G. Downing, Boston, presented a paper on "Cancer of the Skin and Occupational Trauma," which was discussed by Drs. George T. Pack, New York, and Frederick M. Allen, New York.

Dr. Walter C. Lobitz Jr., Hanover, N. H., presented a paper on "Pustular Syringitis: A Sweat Retention Phenomenon Complicating Common Dermatoses." This paper was discussed by Dr. Marion B. Sulzberger, New York.

Dr. William B. Guy, Pittsburgh, presented a paper on "Neurogenic Factors in Contact Dermatitis," which was discussed by Dr. Francis W. Lynch, St. Paul.

Thursday, June 14—Afternoon

The following officers were elected: chairman, Dr. Francis W. Lynch, St. Paul; vice chairman, Dr. E. Myles Standish, Hartford, Conn.; secretary, Dr. John H. Lamb, Oklahoma City; delegate, Dr. Everett C. Fox, Dallas, Texas; alternate, Dr. Leonard F. Weber, Chicago.

Dr. George M. Lewis, New York, presented a report on the American Board of Dermatology.

Dr. Herbert Rattner, Chicago, presented a report on the *Archives of Dermatology and Syphilology*.

Dr. Anthony C. Cipollaro, New York, brought up the matter of education in dermatology at the undergraduate level, which was discussed by Drs. Donald Pillsbury, Philadelphia; Harold N. Cole, Cleveland; Herbert Rattner, Chicago, and Clarence S. Livingood, Galveston, Texas.

On motion regularly made, seconded and carried, it was voted that the chairman of the section appoint a committee to bring in a resolution on the educational matter. Dr. Dalton appointed the following committee: Drs. George M. Lewis, New York; Harold N. Cole, Cleveland; Nelson P. Anderson, Los Angeles, and Anthony C. Cipollaro, New York.

Dr. Harold N. Cole, Cleveland, presented the Guest Lecture, entitled "Erasmus and His Diseases."

Drs. John G. Thomsen and John E. Rauschkolb, Cleveland, presented a paper on "Contact X-ray Therapy of the Common Wart." This paper was discussed by Drs. Frank J. Eichenlaub, Washington, D. C., and John E. Rauschkolb, Cleveland, Ohio.

Drs. Maurice Sullivan and Eugene Bereston, Baltimore, presented a paper on "A Study of Topical Therapy in Tinea Capitis." This paper was discussed by Drs. J. Lamar Callaway, Durham, N. C.; Jacob H. Swartz, Boston; J. Walter Wilson, Los Angeles; George M. Lewis, New York; Albert M. Kligman, Philadelphia; Conrad Stritzler, Jamaica, N. Y., and Eugene Bereston, Baltimore.

Drs. Roy L. Kile, Evelyn Rockwell and Jan Schwarz, Cincinnati, presented a paper on "The Use of Neomycin in Dermatology."

Drs. Clarence S. Livingood, Samchai, Nilasena, J. Fred Mullins and Rufus A. Stevenson, Galveston, Texas, presented a paper on "Pyogenic Infections Treated by Neomycin."

These two papers were discussed by Drs. J. Lowry Miller, New York; Roy L. Kile, Cincinnati; Maurice J. Costello, New York, and Clarence S. Livingood, Galveston, Texas.

Drs. Leslie Paxton Barker and Harry Van Velsor, New York, presented a paper on "Penicillin Treatment of Latent Syphilis: A Study of 110 Cases Previously Treated with Chemotherapy." This paper was discussed by Dr. Herman Beerman, Philadelphia, and Dr. Leslie P. Barker, New York.

Friday, June 15—Afternoon

The delegate to the House of Delegates, Dr. Everett C. Fox, Dallas, Texas, made a report on the activities of the House of Delegates.

Dr. Harold N. Cole read the resolution brought in by a special committee appointed on Thursday, and on motion regularly made, seconded and carried, the resolution was unanimously adopted, as follows:

> Whereas, The American Medical Association is interested in well-trained general practitioners of medicine; and
>
> Whereas, Dermatology and syphilology constitute a large segment of the practice of medicine as a whole; and
>
> Whereas, Eight per cent of all admissions to military hospitals during World War II were dermatological patients; and

WHEREAS, Twelve to fifteen per cent of all questions in Queries and Minor Notes in The Journal of the American Medical Association pertain to dermatology and syphilology; and

WHEREAS, It has come to the attention of this section that there is a wide disparity in regard to the allotment of time devoted to the teaching of dermatology and syphilology, verging almost to complete neglect in some medical colleges; therefore be it

Resolved, That the Section on Dermatology and Syphilology of the American Medical Association deplores the deficient teaching programs of dermatology and syphilology of some medical schools; and be it further

Resolved, That this resolution be brought to the attention of the Board of Trustees of the American Medical Association, of the Council on Medical Education and Hospitals and of the Special Committee on Medical Education.

Dr. Frances Pascher, Brooklyn, presented a paper on "Sternal Marrow Findings in Selected Dermatoses," which was discussed by Drs. Edward P. Cawley, Charlottesville, Va., and Dr. Pascher.

Drs. J. B. Howell, Dallas, Texas, J. Walter Wilson, Los Angeles, and Marcus R. Caro, Chicago, presented a paper on "Tinea Capitis Caused by Trichophyton Tonsurans (Sulfureum or Crateriforme)." This paper was discussed by Drs. Royal M. Montgomery, New York; Everett R. Seale, Houston, Texas, and Walter Wilson, Los Angeles.

Drs. Jeff Davis and George T. Pack, New York, presented a paper on "Erythema Multiforme Following Deep X-Ray Therapy," which was discussed by Drs. Robert N. Buchanan Jr., Nashville, Tenn., and Jeff Davis, New York.

Dr. Isadore I. Fisher, Minneapolis, presented a paper on "Pemphigus Vulgaris: A Clinical and Laboratory Study." This paper was discussed by Drs. Maurice J. Costello, New York, and Isadore I. Fisher, Minneapolis.

Dr. Harold G. Ravitz, St. Paul, presented a paper on "Treatment of Superficial Dermatomycoses with Asterol Dihydrochloride." This paper was discussed by Drs. Jacob H. Swartz, Boston; Bernard Appel, Lynn, Mass.; Robert N. Buchanan Jr., Nashville, Tenn.; Edmond K. Edelson, Newark, N. J.; Everett R. Seale, Houston, Texas, and Harold G. Ravitz, St. Paul.

Dr. Coleman Mopper, Hamtramck, Mich., presented a paper on "Primary Fibrosarcoma of the Skin," which was discussed by Drs. G. W. Binkley, Cleveland; Jeff Davis, New York, and Dr. Mopper.

SECTION ON DISEASES OF THE CHEST

WEDNESDAY, JUNE 13—AFTERNOON

The meeting was called to order by the chairman, Dr. Alvis E. Greer, Houston, Texas.

Dr. Alvis E. Greer presented the chairman's address: "The Evolution of Medicine."

Drs. Hyman E. Bass, David Greenberg, Milton A. Miller and Emanuel Singer, New York, presented a paper on "Pulmonary Changes in Uremia." This paper was discussed by Dr. Esmond R. Long, Philadelphia, and Dr. Hyman E. Bass, New York.

Drs. J. W. Nixon and J. F. Perry, San Antonio, presented a paper on "Modern Trends in the Diagnosis and Treatment of Pulmonary Disease," which was discussed by Dr. Moses J. Stone, Boston, and Dr. Nixon.

Drs. Milton W. Anderson, John R. Kelsey Jr., and Jesse E. Edwards, Rochester, Minn., presented a paper on "Clinical and Pathological Considerations in Patients with Calcific Aortic Stenosis." This paper was discussed by Dr. John F. Briggs, St. Paul, and Dr. Milton W. Anderson, Rochester, Minn.

Dr. O. A. Sander, Milwaukee, read a paper on "Chronic Berylliosis."

Drs. Ralph Horton, Oneonta, N. Y.; Evelyn F. H. Rogers, Utica, N. Y., and Robert F. Korns, Albany, N. Y., presented a paper on "Epidemic of Tuberculosis in a High School." This paper was discussed by Dr. F. M. Pottenger, Monrovia, Calif.

Drs. Herbert C. Sweet and Paul Murphy, St. Louis, presented a paper on "The Evaluation of Therapy in Pulmonary Emphysema," which was discussed by Dr. Leon H. Hirsch, Milwaukee.

Drs. Michael E. DeBakey, Houston, Texas, and Alton Ochsner, Paul T. DeCamp and C. J. Ray, New Orleans, presented a paper on "Bronchogenic Carcinoma with Particular Emphasis on Its Incidence and Early Manifestations." This paper was discussed by Dr. John F. Briggs, St. Paul, and Dr. Michael E. DeBakey, Houston, Texas.

THURSDAY, JUNE 14—AFTERNOON

The following officers were elected: chairman, Dr. J. Winthrop Peabody, Washington, D. C.; vice chairman, Dr. Joseph C. Placak, Cleveland; delegate, Dr. Hollis E. Johnson, Nashville, Tenn.; alternate, Dr. Edward Hayes, Monrovia, Calif. The secretary, Dr. Jay A. Myers, Minneapolis, continues for another year.

Drs. Burgess Gordon, Hurley L. Motley and Peter A. Theodos, Philadelphia, presented a paper on "The Use of Intermittent Positive Pressure Breathing and Streptomycin in the Management of Chronic Pulmonary Tuberculosis Complicating Silicosis." This paper was discussed by Dr. Edwin R. Levine, Chicago, and Dr. Burgess Gordon, Philadelphia.

Dr. Robert J. Anderson, Washington, D. C., read a paper on "Community-Wide X-Ray Surveys in Big Cities," which was discussed by Drs. Otto L. Bettag, Chicago; Frank J. Hill, Minneapolis, and Robert J. Anderson, Washington, D. C.

Dr. Herman J. Moersch, Rochester, Minn., read a paper on "The Significance of Hemoptysis," which was discussed by Drs. Porter P. Vinson, Richmond, Va., and Henry Scheer, New York.

Dr. Andrew L. Banyai, Milwaukee, read a paper on "The Management of Cough in Daily Practice."

Drs. Abraham Falk, and W. T. Tucker, Minneapolis, read a paper on "Clinical Implications of Idiopathic Pleural Effusions." This paper was discussed by Drs. Lee Ogden, New York, and W. T. Tucker, Minneapolis.

Dr. Daniel J. Glomset, Des Moines, Iowa, read a paper on "Cardiac Conduction," which was discussed by Dr. A. E. Jaffin, Jersey City, N. J., and Dr. Glomset.

FRIDAY, JUNE 15—AFTERNOON

Dr. William S. Schwartz, Oteen, N. C., read a paper on "Recent Drug Therapy in Diseases of the Chest," which was discussed by Drs. Harold L. Israel, Philadelphia, and William S. Schwartz, Oteen, N. C.

Dr. John F. Briggs, St. Paul, read a paper on "The Diagnosis and Treatment of Coronary Heart Disease." This paper was discussed by Drs. Harry Golston, Hartford, Conn.; Benjamin Miller, Baltimore, and John F. Briggs, St. Paul.

Dr. Philip Thorek, Chicago, read a paper on "Modern Diagnosis and Treatment of Esophageal Diseases," which was discussed by Drs. John F. Briggs, St. Paul, and Philip Thorek, Chicago.

Dr. Hobart A. Reimann, Philadelphia, read a paper on "The Differential Diagnosis of the Pneumonias."

SECTION ON EXPERIMENTAL MEDICINE AND THERAPEUTICS

WEDNESDAY, JUNE 13—AFTERNOON

The meeting was called to order at 2:05 p. m. by the chairman, Dr. James A. Greene, Houston, Texas.

The following papers were read as a symposium on "Liver Disease."

Drs. Joseph Stokes Jr., Miles E. Drake and John Farquhar, Philadelphia, and Mercer C. Blanchard, Columbus, Ga.: "Further Studies on the Epidemiology of Viral Hepatitis." This paper was discussed by Drs. W. P. Havens, Philadelphia, and Richard B. Capps, Chicago.

Drs. Victor M. Sborov and Theodore C. Keller, Washington, D. C.: "The Diagnosis of Hepatitis." This paper was discussed by Drs. Hans L. Popper and Richard B. Capps, Chicago.

Dr. John R. Neefe, Philadelphia: "Current Concepts of Treatment of Hepatitis." This paper was discussed by Drs. Franklin M. Hanger, New York, and F. J. Ingelfinger, Boston.

Dr. Henry G. Kunkel, New York: "The Fate of the Patient with Hepatitis." This paper was discussed by Dr. Joseph Post, New York.

Drs. J. T. Sessions Jr., Boston; J. C. Bullard, Framingham, Mass., and F. J. Ingelfinger, Boston: "The Effect of Barbiturates in Patients with Liver Disease." This paper was discussed by Drs. Jesse L. Bollman, Rochester, Minn.; E. M. Papper, New York, and James A. Greene, Houston, Texas.

Drs. Theodore B. Van Itallie and Frederick J. Stare, Boston: "The Clinical Use of Fat Injected Intravenously." This paper was discussed by Drs. Robert Elman, St. Louis; Jonathan E. Rhoads, Philadelphia, and Laurance W. Kinsell, Oakland, Calif.

Thursday, June 14—Afternoon

The following officers were elected: chairman, Dr. Carl V. Moore, St. Louis; vice chairman, Dr. Maurice H. Seevers, Ann Arbor, Mich.; secretary, Dr. Hugh R. Butt, Rochester, Minn.; delegate, Dr. Edgar V. Allen, Rochester, Minn.; alternate, Dr. Charles M. Gruber, Philadelphia; representative to the Scientific Exhibit, Dr. Robert W. Wilkins, Boston.

Dr. James A. Greene, Houston, Texas, presented the chairman's address on "Pituitary Dwarfism, a Therapeutic Dilemma."

Dr. William B. Castle, Boston, presented the Minot Lecture: "The Contributions of George Richards Minot to Experimental Medicine."

Drs. Ernest Yount, Marvin Rosenblum, and Robert L. McMillan, Winston-Salem, N. C., presented a paper on "Therapeutic Use of Quinidine: The Value of Blood Levels in Treatment." This paper was discussed by Drs. J. Edwin Wood Jr., Charlottesville, Va., and Harold Feil, Cleveland.

Dr. Marsh H. McCall, Samuel Musallam and Guillermo Porras, New York, prsented a paper on "Anticoagulant Therapy in Acute Myocardial Infarction," which was discussed by Drs. Nelson W. Barker, Rochester, Minn.; George C. Griffith, Pasadena, Calif.; Samuel Baer, Philadelphia, and E. S. Nichol, Miami.

Drs. Nelson W. Barker, Hugh H. Hanson, and Frank D. Mann, Rochester, Minn., presented a paper on "Comparative Effects of the Anticoagulants Dicumarol, Tromexan and 4-Hydroxy-Coumarin Anticoagulant 63." This paper was discussed by Drs. Shepard Shapiro, New York, and Charles Brambel, Baltimore.

Drs. Harrison F. Flippin and William P. Boger Jr., Philadelphia, presented a paper on "Present Day Treatment of Pneumonia," which was discussed by Dr. John Staige Davis, New York.

Friday, June 15—Morning

A joint meeting was held with the Section on Internal Medicine. The proceedings are reported in the minutes of that section.

SECTION ON GASTRO-ENTEROLOGY AND PROCTOLOGY

Wednesday, June 13—Afternoon

The meeting was called to order at 2 o'clock by the chairman, Dr. Frank G. Runyeon, Reading, Pa.

Dr. Benjamin M. Bernstein, Brooklyn, read a paper entitled "Acidity: Is It Related to Ulcer Syndrome?" This paper was discussed by Dr. Hyman I. Goldstein, Camden, N. J.

A paper entitled "Banthine: Clinical Evaluation in Gastro-Enterology," by Dr. Gordon McHardy, New Orleans, was presented and was discussed by Dr. Asher Winkelstein, New York; Dr. Cecil O. Patterson, Dallas, Texas; Dr. William P. Chapman, Boston; Dr. Henry A. Rafsky, New York; Dr. Erwin Levin, Chicago; Dr. Keith S. Grimson, Durham, N. C.; Dr. Benjamin M. Bernstein, New York, and Dr. Gordon McHardy, New Orleans.

Dr. Moses Paulson, Baltimore, read a paper entitled "Syndrome Following Total Gastrectomy," which was discussed by Dr. Dwight L. Wilbur, San Francisco; Dr. Thomas E. Machella, Philadelphia, and Dr. Moses Paulson, Baltimore.

Dr. Clifford J. Barborka, Chicago, presented a paper on the "Present Status of the Obesity Problem." This paper was discussed by Dr. James S. McLester, Birmingham, Ala.; Dr. Bruce Kenamore, St. Louis, and Dr. Clifford J. Barborka, Chicago.

A paper entitled "Gastric Polyps" was presented by Drs. Harry Yarnis and Richard H. Marshak, New York, and Dr. A. I. Friedman, Hackensack, N. J., and was discussed by Dr. James B. Carey, Minneapolis; Dr. Saul A. Schwartz, New York, and Dr. A. I. Friedman, Hackensack, N. J.

Drs. Max Ritvo, Norman Zamcheck, Melvin P. Osborne, Franklin W. White,* and Thomas C. Chalmers, Boston, and Max G. Carter, New Haven, Conn., presented a paper entitled "Early Diagnosis in Massive Upper Gastrointestinal Hemorrhage." This paper was discussed by Dr. A. H. Aaron, Buffalo; Dr. Fred E. Templeton, Seattle; Dr. Hyman I. Goldstein, Camden, N. J.; Dr. John T. Howard, Baltimore, and Dr. Norman Zamcheck, Boston.

Thursday, June 14—Afternoon

The following officers were elected: chairman, Dr. Grant H. Laing, Chicago; vice chairman, Dr. Louis E. Moon, Omaha; secretary, Dr. Donovan C. Browne, New Orleans; chairman, section committee on scientific exhibits, Dr. Everett D. Kiefer, Boston, and co-chairman, Dr. J. P. Nesselrod, Evanston, Ill.; representative to American Board of Proctology, Dr. Robert A. Scarborough, San Francisco.

Dr. A. H. Aaron, Buffalo, representative to the American Board of Gastro-Enterology, made his report, and Dr. Robert A. Scarborough, representative to the American Board of Proctology, gave a report.

A paper entitled "Adenomas of the Colon and Rectum" by Drs. George E. Binkley and Douglas A. Sunderland, New York, was presented, and was discussed by Drs. Harry E. Bacon, Philadelphia, and Robert A. Scarborough, San Francisco.

Drs. Sidney A. Portis and Joseph C. King, Chicago, presented a paper entitled "The Gastrointestinal Tract in the Aging." This paper was discussed by Drs. Martin S. Kleckner, Allentown, Pa.; Henry A. Rafsky, New York; Anthony Bassler, New York, and Sidney A. Portis, Chicago.

Dr. Frank G. Runyeon, Reading, Pa., read the chairman's address, entitled "Sigmoidoscopy: Its Clinical Importance to the Practitioner."

A paper entitled "ACTH in the Treatment of Ulcerative Colitis" was presented by Drs. Seymour J. Gray, Robert W. Reifenstein, J. C. Gordon Young, John A. Benson Jr., and Kenneth Sterling, Boston, and was discussed by Drs. J. Arnold Bargen, Rochester, Minn., and Franz J. Ingelfinger, Everett D. Kiefer and Seymour J. Gray, Boston.

A paper entitled "Multiple Polyposis: Results of Fulguration of Polyps in the Distal Portion of the Colon After Ileosigmoidostomy and Colectomy," was presented by Drs. Newton D. Smith and John R. Hill, Rochester, Minn. This paper was discussed by Dr. Garnet W. Ault, Washington, D. C.; Dr. Stuart T. Ross, Hempstead, N. Y., and Dr. Newton D. Smith, Rochester, Minn.

Drs. Maurice Feldman and Tobias Weinberg, Baltimore, presented a paper entitled "Aberrant Pancreas, a Cause of Duodenal Syndrome," which was discussed by Dr. Russell S. Boles, Philadelphia; Dr. Sara M. Jordan, Boston, and Dr. Maurice Feldman, Baltimore.

Friday, June 15—Morning

A joint meeting was held with the Section on Pathology and Physiology. The proceedings are reported in the minutes of that section.

SECTION ON GENERAL PRACTICE

Wednesday, June 13—Morning

The meeting was called to order at 9 o'clock by the chairman, Dr. Lester D. Bibler, Indianapolis.

Dr. Lester D. Bibler, Indianapolis, presented the "Chairman's Address."

Dr. David I. Macht, Baltimore, read a paper on "Influence of Some Medicinal and Emotional Factors on Blood Coagulation," which was discussed by Drs. Geza de Takats, Chicago, and David I. Macht, Baltimore.

Dr. Claude S. Beck, Cleveland, read a paper on "Operation for Coronary Artery Disease," which was discussed by Drs. George D. Geckeler, Philadelphia; N. A. Antonius, Newark, N. J.; Charles P. Bailey, Philadelphia; Harold Feil, Cleveland; Egmont J. Orbach, New Britain, Conn., and Claude S. Beck, Cleveland.

---

* Deceased.

Dr. Russell S. Boles, Philadelphia, read a paper on "The Responsibility of the Physician to His Patient," which was discussed by Dr. Thomas E. Robinson, Salt Lake City.

Dr. Thomas E. Rardin, Columbus, Ohio, read a paper on "Psychosomatic Highlights."

Dr. William A. Schonfeld, New York, read a paper on "The General Practitioner's Role in the Management of Personality Problems of the Adolescent." This paper was discussed by Drs. Camille K. Cayley, New York; Herbert F. Robb, Belleville, Mich., and William A. Schonfeld, New York.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. Thomas E. Robinson, Salt Lake City; vice chairman, Dr. Richard A. Mills, Fort Lauderdale, Fla.; secretary, Dr. Eugene Baumgartner, Oakland, Md.; chairman, scientific exhibit, Dr. Charles E. McArthur, Olympia, Wash.

On motion of Dr. Thomas E. Robinson, Salt Lake City, seconded by Dr. Milton B. Casebolt, Kansas City, Mo., the following resolution was passed:

A RESOLUTION TO THE BOARD OF TRUSTEES FROM THE SECTION ON GENERAL PRACTICE

WHEREAS, The Board of Trustees in its respected and judicious decision created a Section on General Practice; and

WHEREAS, This section fills a long needed place for the free exchange of information among all men in all branches of medicine; and

WHEREAS, A large proportion of the industrial and accidental work is done by the general practitioner; now therefore be it

Resolved, That we as a section petition and ask that the Board of Trustees of the American Medical Association place a member of the Section on General Practice on the Council on Industrial Health.

Dr. William B. Norment, Greensboro, N. C., read a paper on "Diagnosis and Treatment of Pathology of the Uterine Canal with the Lens Hysteroscope."

Dr. Edward A. Schumann, Philadelphia, read a paper on "Obstetric Hemorrhage," which was discussed by Drs. Daniel H. Hiebert, Provincetown, Mass.; Ellis M. Markell, Harrison, N. Y., and Edward A. Schumann, Philadelphia.

Dr. Daniel B. Dorman, Pittsfield, Mass., read a paper on "The Management of the Abnormal Presentation During the Second Stage of Labor," which was discussed by Drs. J. Edward Lynch and Milton L. McCall, Philadelphia, and Daniel B. Dorman, Pittsfield, Mass.

Drs. F. Bayard Carter, Violet H. Turner, Clarence C. Davis and Edwin C. Hamblen, Durham, N. C., presented a paper on "Comparison of Previous Operations and Initial Pathology in Five Hundred Childless Couples." This paper was discussed by Drs. M. Edward Davis, Chicago; Fred A. Simmons, Boston, and Clarence C. Davis, Durham, N. C.

Dr. U. R. Bryner, Salt Lake City, read a paper on "An Evaluation of Socialized Medicine in Great Britain as Seen by a Member of the American Medical Association Committee." This was discussed by Drs. Morgan D. Person, Allentown, Pa., and U. R. Bryner, Salt Lake City.

FRIDAY, JUNE 15—MORNING

Dr. Robert Turell, New York, read a paper on "Proctology and the General Practitioner," which was discussed by Drs. A. A. Gladstone, Burlington, Vt.; F. H. Redewill, San Francisco; Richard I. Barstow, Norfolk, Conn., and Robert Turell, New York.

Dr. Milton B. Casebolt, Kansas City, Mo., read a paper on "Geriatrics: A Challenge to the General Practitioner."

Dr. F. H. Redewill, San Francisco, read a paper on "Biological Warfare."

Dr. W. J. Merle Scott, Rochester, N. Y., read a paper on "Clinical Results of Treatment by Aero-Pulse Principle in Postphlebitis and Varicose Venous Stasis." This paper was discussed by Drs. William F. Clark, Rochester, N. Y.; Thomas E. Robinson, Salt Lake City; Leo M. Boden, East Aurora, N. Y.; R. M. Cunningham, Baltimore, Md., and W. J. Merle Scott, Rochester, N. Y.

Dr. Burech Rachlis, Philadelphia, read a paper on "Vertigo," which was discussed by Drs. Matthew S. Ersner, Michael Scott and Burech Rachlis, Philadelphia.

Dr. Benjamin F. Byrd, Nashville, Tenn., read a paper on "The Fatal Pause in Diagnosis of Neoplastic Disease in the Physician Patient." This paper was discussed by Drs. James C. Kimbrough, Washington, D. C.; Richard M. Taliafero, Greensboro, N. C., and Benjamin F. Byrd, Nashville, Tenn.

SECTION ON INTERNAL MEDICINE

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr. Walter L. Palmer, Chicago.

Drs. Charles C. Wolferth, William A. Jeffers, Francis D. W. Lukens, Harold A. Zintel and Joseph H. Hafkenschiel, Philadelphia, presented a paper on "Subtotal Adrenalectomy in the Treatment of Arterial Hypertension." This paper was discussed by Drs. D. M. Green, Chicago, and Reginald H. Smithwick, Boston.

Drs. Thomas P. Lyon, John W. Gofman, Frank Lindgren and Hardin Jones, Berkeley, Calif., presented a paper on "Further Studies of the Relationship of Lipoproteins to Atherosclerosis." This paper was discussed by Drs. Louis N. Katz, Chicago, and W. C. Hueper, Bethesda, Md.

Dr. N. C. Gilbert, Chicago, delivered the Billings Lecture: "A History of the Treatment of Coronary Heart Disease."

Dr. Robert L. Levy, New York, presented a paper on "Needless Restrictions Imposed on Cardiac Patients," which was discussed by Drs. Henry A. Christian, Brookline, Mass.; John J. Sampson, San Francisco, and Hyman I. Goldstein, Camden, N. J.

Drs. Arthur M. Master and Harry L. Jaffe, New York, presented a paper on "Complete Functional Recovery from Acute Coronary Occlusion and Insufficiency." This paper was discussed by Drs. George C. Griffith, Pasadena, Calif.; A. Carlton Ernstene, Cleveland, and Hyman I. Goldstein, Camden, N. J.

Drs. J. Edwin Wood Jr., Donald H. Ferguson and Preston B. Lowrance, Charlottesville, Va., presented a paper on "Cation Exchange Resins as an Adjunct in the Treatment of Heart Failure." This paper was discussed by Drs. Edward S. Orgain, Durham, N. C., and J. Russell Elkinton, Philadelphia.

Dr. Fay A. LeFevre, Cleveland, presented a paper on "The Management of Occlusive Arterial Disease of the Extremities," which was discussed by Drs. Robert W. Wilkins, Boston; Milton Mendlowitz, New York; William S. Collens, Brooklyn, and Benjamin Jablons, New York.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. Carter Smith, Atlanta, Ga.; vice chairman, Dr. Truman G. Schnabel, Philadelphia; secretary, Dr. Herrman L. Blumgart, Boston; delegate, Dr. Charles T. Stone, Galveston, Texas; alternate, Dr. William D. Stroud, Philadelphia.

Drs. Paul S. Rhoads, Carl E. Billings and Vincent J. O'Conor, Chicago, presented a paper on "Problems in the Management of Urinary Tract Infections," which was discussed by Drs. Ernest E. Irons, Chicago, and Edward N. Cook, Rochester, Minn.

Dr. Emanuel Schwartz, Brooklyn, presented a paper on "Oral Cortisone in Intractable Bronchial Asthma," which was discussed by Drs. Carl E. Arbesman, Buffalo, and Theron G. Randolph and Walter L. Palmer, Chicago.

Dr. Walter L. Palmer, Chicago, Ill., presented the chairman's address on "Medical and Social Aspects of Problems of Population."

Drs. Lawrence E. Hinkle Jr., and Stewart G. Wolf Jr., New York, presented a paper on "The Importance of Life Stress in the Course and Management of Diabetes Mellitus." This paper was discussed by Drs. Edward Tolstoi, New York, and Garfield G. Duncan, Philadelphia.

Dr. Marc J. Musser, Madison, Wis., presented a paper on "Some Factors in the Early Diagnosis of Emotionally Conditioned Illness," which was discussed by Drs. Grete L. Bibring, Boston; Edward Weiss, Philadelphia, and Eugene Ziskind, Los Angeles.

FRIDAY, JUNE 15—MORNING

Joint Meeting with Section on Experimental Medicine and Therapeutics

The joint meeting was called to order at 9 o'clock by the chairman of the Section on Experimental Medicine and Therapeutics, Dr. James A. Greene, Houston, Texas.

All of the papers read at this joint meeting were presented as a "Symposium on Arteriosclerosis and Hypertension."

Dr. Herbert Chasis, New York, presented a paper on "Pathogenesis of Hypertension," which was discussed by Dr. Stanley E. Bradley, New York.

Dr. Louis N. Katz, Chicago, presented a paper on "Newer Approaches to the Pathogenesis of Atherosclerosis."

Dr. William B. Wartman, Chicago, presented a paper on "The Pathology of Arteriosclerosis." This paper was discussed by Drs. H. T. Blumenthal, St. Louis, and L. L. Waters, New Haven, Conn.

Dr. Ancel Keys, Minneapolis, presented a paper on "Cholesterol, Giant Molecules and Atherosclerosis," which was discussed by Dr. Irvine H. Page, Cleveland.

Drs. Howard Burchell, E. V. Allen and F. P. Moersch, Rochester, Minn., presented a paper on "The Clinical Manifestations of Arteriosclerosis." This paper was discussed by Drs. Francis M. Forster, Washington, D. C.; Francis C. Wood, Philadelphia, and Louis N. Katz, Chicago.

Dr. Irvine H. Page, Cleveland, presented a paper on "Current Treatment of Hypertension," which was discussed by Drs. Robbert W. Wilkins, Boston; Frederick M. Allen, New York, and Herbert Chasis, New York.

SECTION ON LARYNGOLOGY, OTOLOGY AND RHINOLOGY

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr. J. Milton Robb, Detroit.

Drs. Edmund P. Fowler and Adolf Zeckel, New York, presented a paper on "Psychosomatic Aspects of Ménière's Disease." This paper was discussed by Drs. Adolf Zeckel, New York, and Norton Canfield, New Haven, Conn.

Drs. Francis H. McGovern, Danville, Va., and G. Slaughter Fitz-Hugh, Charlottesville, Va., presented a paper on "Herpes Zoster of the Cephalic Extremity." On motion of Dr. Edmund P. Fowler, seconded by Dr. Norton Canfield, New Haven, Conn., it was voted to allow Dr. William C. Thornell, Cincinnati, to read the discussion of this paper, prepared by Dr. Kurt Tschiassny, Cincinnati, who was unable to be present.

Dr. Marvin F. Jones, New York, presented a paper on "Allergy of the Upper Respiratory Tract: Its Cure by Surgery Plus Antiallergic Methods." This paper was discussed by Drs. Irving W. Voorhees and L. L. Coleman, New York; Sacks Bricker, Philadelphia, and Henry M. Scheer, New York.

Drs. Frederick R. Guilford, Houston, Texas, and C. O. Haug, Galveston, Texas, presented a paper on "The Diagnosis of Deafness in the Very Young Child Aided by the Use of a New Instrument, the Pediacoumeter." This paper was discussed by Drs. Edmund P. Fowler, New York; Stanley Macht, Hagerstown, Md.; Sam H. Sanders, Memphis, Tenn., and Frederick R. Guilford, Houston, Texas.

Dr. Raymond E. Jordan, Pittsburgh, presented a paper on "The Role of Allergy in Otology," which was discussed by Drs. Erhart Ruedemann, Pittsburgh; Francis Davison, Danville, Pa., and Raymond E. Jordan, Pittsburgh.

THURSDAY, JUNE 14—MORNING

Dr. Gordon F. Harkness, Davenport, Iowa, gave his report as delegate to the House of Delegates.

The following officers were elected: chairman, Dr. Carl H. McCaskey, Indianapolis; vice chairman, Dr. Fred W. Dixon, Cleveland; secretary, Dr. Sam H. Sanders, Memphis, Tenn.; representative to the Scientific Exhibit, Dr. Francis W. Davison, Danville, Pa., and representative to the American College of Surgeons, Dr. Louis H. Clerf, Philadelphia.

Dr. O. E. Hallberg, Rochester, Minn., presented a paper on "Nosebleed and Its Treatment," which was discussed by Drs. D. H. Anthony, Memphis, Tenn.; William C. Thornell, Cincinnati; Hyman I. Goldstein, Camden, N. J.; Joseph I. Kemler, Baltimore; John J. Rainey, Troy, N. Y.; Ernest Reeves, Passaic, N. J., and O. E. Hallberg, Rochester, Minn.

Dr. De Graaf Woodman, New York, presented a paper on "Congenital Atresia of the Auditory Canal," which was discussed by Drs. George L. Pattee, Denver; Edgar M. Holmes, Boston; Frederick R. Guilford, Houston, Texas, and De Graaf Woodman, New York.

Dr. J. Milton Robb, Detroit, read his chairman's address, "Are You an Otolaryngologist?"

Dr. I. Mathews Robison, Houston, Texas, presented a paper on "Pressure Treatment of Maxillary Sinusitis." This paper was discussed by Dr. George S. McReynolds, Galveston, Texas.

The chairman, Dr. J. Milton Robb, read a report from the American Board of Otolaryngology.

FRIDAY, JUNE 15—MORNING

Dr. Daniel C. Moore, Seattle, presented a paper on "A Technic of Anesthesia for Long and/or Technically Difficult Ophthalmologic and Otolaryngologic Surgical Procedures." This paper was discussed by Drs. Paul B. MacCready, New Haven, Conn.; P. L. Munday, Camp Carson, Colo.; Joseph I. Kemler, Baltimore, Md.; Frank D. Lathrop, Boston; James B. Costen, St. Louis; Henry M. Scheer, New York, and Daniel C. Moore, Seattle.

Dr. Gabriel F. Tucker, Philadelphia, presented a paper on "Diagnosis and Treatment of Cancer of the Larynx: Methods of Cure: Median Thyrotomy, Laryngectomy, Irradiation and Irradiation with Surgery." This paper was discussed by Drs. Edwin N. Broyles, Baltimore; Murdock S. Equen, Atlanta, Ga.; Joseph I. Kemler, Baltimore; Frederick M. Allen, New York; Henry B. Orton, Newark, N. J., and Gabriel F. Tucker, Philadelphia.

Drs. Lawrence Reynolds, K. E. Corrigan and H. S. Hayden, Detroit, presented a paper on "Use of Radioactive Isotopes for Differential Diagnosis of Malignant and Nonmalignant Lesions in the Throat," which was discussed by Drs. Wadsworth Warren and J. Milton Robb, Detroit.

Dr. Bruce Proctor, Detroit, presented a paper on "Surgical Anatomy of the Neck." This paper was discussed by Drs. James E. Croushore, Detroit, and Henry B. Orton, Newark, N. J.

SECTION ON MISCELLANEOUS TOPICS

Session on Allergy

WEDNESDAY, JUNE 13—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr. Samuel M. Feinberg, Chicago.

A round table discussion on "ACTH and Cortisone in Allergic Diseases" was conducted by Dr. Robert A. Cooke and Dr. Marion B. Sulzberger, New York.

Dr. John H. Mitchell, Columbus, Ohio, presented a paper on "Antihistamines in Allergic Disorder," which was discussed by Dr. Carl E. Arbesman, Buffalo, and Dr. Mitchell.

Dr. Samuel M. Feinberg, Chicago, delivered the chairman's address: "Allergy Therapy; Some Common Misconceptions," which was discussed by Dr. Horace S. Baldwin, New York.

Dr. Oren C. Durham, Chicago, read a paper on "Pollen Prevalence and Pollen-Free Areas." This paper was discussed by Dr. Lawrence J. Halpin, Cedar Rapids, Iowa.

Drs. Karl D. Figley and Frank F. A. Rawling, Toledo, Ohio, presented a paper on "Diagnostic Methods in Food Allergy," which was discussed by Dr. Mary H. Loveless, New York.

Sessions on Military Medicine

THURSDAY, JUNE 14—AFTERNOON

The meeting was called to order at 2:10 p. m. by the chairman, Dr. Russel V. Lee, Palo Alto, Calif.

Dr. Richard L. Meiling, Washington, D. C., presented a paper on "The Changing Military Medical Picture in the United

States of America." This paper was discussed by Drs. Paul I. Robinson; Harry Armstrong, and H. Lamont Pugh, Washington, D. C.

Dr. E. R. Hering, Korea, read a paper on "Combat Medical Experience," which was discussed by Drs. Oral B. Bolibaugh, San Francisco, and William D. Preston, Washington, D. C.

Dr. Truman Blocker, Galveston, Texas, read a paper on "Treatment of Burns." This paper was discussed by Drs. Edwin J. Pulaski, San Antonio, Texas; Everett I. Evans, Richmond, Va.; Paul E. Spangler, Norfolk, Va., and Frederick M. Allen, New York.

Dr. Bertram Groesbeck, Washington, D. C. read a paper on "Survival, Rescue and Resuscitation." This paper was discussed by Drs. Ray G. Daggs, Fort Knox, Ky., and Alonzo A. Towner, Washington, D. C.

Dr. Howard A. Rusk, New York, read a paper on "Procurement, Assignment and Utilization of Reserve Medical Officers," which was discussed by Drs. Paul I. Robinson, Wallace H. Graham, and C. W. Stelle, Washington, D. C.

A paper on "Cold Injuries with Emphasis on Frostbite" was presented. This paper was discussed by Drs. Everett Homer Dickinson, Oakland, Calif.; Kurt Lange, New York; Francis S. Adams, Pueblo, Colo.; Robert B. Lewis, Randolph Field, Texas, and Kenneth D. Orr, U. S. Army.

FRIDAY, JUNE 15—AFTERNOON

The meeting was called to order at 2 o'clock by the vice chairman, Dr. Francis B. Berry, New York.

Dr. Wilfred Hall, Washington, D. C., presented a paper on "Air Evacuation," which was discussed by Drs. Bertram Groesbeck, Washington, D. C., and Byron L. Steger, Baltimore.

Dr. Thomas L. Willmon, New London, Conn., presented a paper on "Man and the Submarine," which was discussed by Dr. Ebbe C. Hoff, Richmond, Va.

Dr. James J. Sapero, Cairo, Egypt, presented a paper on "Communicable Diseases of Africa and the Middle East." This paper was discussed by Dr. Joseph E. Smadel and Dr. John S. Paul, Washington, D. C.

Dr. Edward J. Kendricks, Washington, D. C., presented a paper on "Practical Problems in Aviation Medicine," which was discussed by Dr. Ashton Graybiel, Pensacola, Fla.

Dr. Franklin C. McLean, Chicago, presented a paper on "Progress in the Prevention and Treatment of Radiation Injury." This paper was discussed by Dr. Harry H. Haight, Washington, D. C.

Dr. August W. Spittler, Washington, D. C. presented a paper on "Orthopedic Problems in the Field," which was discussed by Drs. Chalmers Carr, Washington, D. C., and Oscar Reeder, Phoenixville, Pa.

The chairman announced that the Council on Scientific Assembly had agreed to appoint the following physicians as officers of the newly formed Section on Military Medicine: Chairman, Dr. Melvin A. Casberg, St. Louis; vice chairman, Dr. Richard A. Kern, Philadelphia; secretary, Dr. Sheldon S. Brownton, Fort Slocum, N. Y.

Dr. Russel V. Lee, Palo Alto, Calif., was elected delegate.

SECTION ON NERVOUS AND MENTAL DISEASES

WEDNESDAY, JUNE 13—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr. Louis J. Karnosh, Cleveland.

A paper entitled "Psychiatric Treatment in General Hospitals in the United States and Canada," was presented by Drs. A. E. Bennett, Bernice Engle, and Eugene A. Hargrove, Berkeley, Calif. This paper was discussed by Drs. Baldwin L. Keyes, Philadelphia, and A. E. Bennett, Berkeley, Calif.

Dr. Eugene Ziskind, Los Angeles, read a paper entitled "The Cure of Emotional and Social Etiological Factors in Medical Patients." This paper was discussed by Dr. James P. Scanlon, Washington, D. C., and Dr. Ziskind.

Dr. Edward A. Strecker, Philadelphia, read a paper entitled "Therapeutic Aspects of Alcoholism," which was discussed by Drs. Frederick Lemere, Seattle; Robert V. Seliger, Baltimore; Arthur M. Sackler, New York and Dr. Strecker.

A "Report of the Section Committee Concerning the Licensure or Certification of Clinical Psychologists," was presented by Dr. Francis J. Gerty, Mr. J. W. Holloway and Dr. R. P. Mackay, Chicago.

A paper entitled "The Psychiatric Manifestations of Acute Pancreatitis," was presented by Drs. Charles Savage and Wendell A. Butcher, Bethesda, Md., and Douglas Noble, Washington, D. C., and was discussed by Drs. Edward Weiss, Philadelphia; George N. Raines, Washington, D. C., and Dr. Noble.

Drs. Robert A. Matthews and Ian P. Stevenson, New Orleans, presented a paper entitled "Theory and Fact in Psychosomatic Medicine." This paper was discussed by Drs. David McK. Rioch, Washington, D. C.; Francis J. Gerty, Chicago, and Dr. Stevenson.

A paper entitled "The Psychiatric Aspects of Cortisone and ACTH Administration," was presented by Drs. Francis J. Braceland and Howard P. Rome, Rochester, Minn., and was discussed by Dr. Cecil L. Wittson, Omaha, and Dr. Braceland.

THURSDAY, JUNE 14—AFTERNOON

The following officers were elected: chairman, Dr. Frank H. Luton, Nashville, Tenn.; vice chairman, Dr. A. Earl Walker, Baltimore; secretary, Dr. Francis M. Forster, Washington, D. C.; representative to American Board of Psychiatry and Neurology, Dr. Francis J. Gerty, Chicago; delegate, Dr. Hans H. Reese, Madison, Wis.; alternate delegate, Dr. Paul C. Bucy, Chicago; chairman of Scientific Exhibits, Dr. Leon Whitsell, San Francisco.

On motion of Dr. George N. Raines, Washington, D. C., seconded by Dr. Percival Bailey, Chicago, it was voted unanimously to accept the report of the Section Committee Concerning the Licensure or Certification of Clinical Psychologists as an expression of the point of view of the section, and that the report be transmitted to the Director of the Bureau of Legal Medicine and Legislation of the American Medical Association, with the recommendation that it be adopted as the official point of view of the American Medical Association and be implemented by appropriate action of the American Medical Association.

On motion of Dr. Robert T. Morse, Washington, D. C., seconded by Dr. Daniel Blain, Washington, D. C., it was voted unanimously that the chairman appoint a committee of not less than three or more than five members to serve, through the annual session in 1954, in an advisory capacity to the Bureau of Legal Medicine and Legislation of the American Medical Association and to report to the Section at each annual session on matters pertaining to the legal control and practice of clinical psychology.

Dr. Percival Bailey, Chicago, section delegate, reported on actions of the House of Delegates.

A motion by Dr. Roland P. Mackay, Chicago, to request the House of Delegates not to change the name of the section was duly seconded and carried.

Dr. Francis J. Braceland, Rochester, Minn., gave a report on the American Board of Psychiatry and Neurology.

Dr. Francis M. Forster, secretary, read a report on the American Board of Neurology.

Dr. Percival Bailey, Chicago, presented a resolution requesting the House of Delegates to seek legislation permitting civilians with severe transverse lesions of the spinal cord to be admitted to paraplegic wards of veterans hospitals. The resolution was adopted on motion duly made, seconded and carried.

Dr. Louis J. Karnosh, Cleveland, presented the chairman's address, "Neurology and Human Emotions."

Dr. Alexander T. Ross, Indianapolis, read a paper on "Comparative Incidence of Residual Defects Following Serum, Sulfonamide and Sulfapenicillin Therapy for Meningococcic Meningitis." This paper was discussed by Drs. Ellsworth C. Alvord, Washington, D. C.; Roland P. Mackay, Chicago, and Dr. Ross.

A paper entitled "The Effects of Pituitary Adrenocorticotropic Hormone (ACTH) and Cortisone on Disorders of the Nervous System," was presented by Drs. Gilbert H. Glaser and H. Houston Merritt, New York, and was discussed by Drs. Donald McEachern, Montreal, Can.; Roland P. Mackay, Chicago; Nathan S. Schlezinger, Philadelphia, and Drs. Merritt and Glaser.

Drs. Morris J. Tissenbaum, Harry M. Harter and Arnold P. Friedman, New York, presented a paper entitled "Organic Neurologic Syndromes Diagnosed as Functional Disorders." This paper was discussed by Drs. Russell M. DeJong, Ann Arbor, Mich.; Johannes M. Nielsen, Los Angeles, and Dr. Friedman.

Dr. Elinor R. Ives, Los Angeles, read a paper on "Comparison of the Efficacy of Various Drugs in the Treatment of Epilepsy," which was discussed by Drs. Jerome K. Merlis, Framingham, Mass.; Daniel Sciarra, New York, and David R. Talbot, San Diego, Calif.

Dr. Nathan S. Schlezinger, Philadelphia, read a paper entitled "The Present Status of Therapy in Myasthenia Gravis." This paper was discussed by Drs. Robert S. Schwab, Boston; Clark H. Millikan, Rochester, Minn., and Dr. Schlezinger.

FRIDAY, JUNE 15—AFTERNOON

The chairman appointed the following as a committee to serve in connection with the program outlined by the special Committee on Licensure or Certification of Clinical Psychologists: Dr. Daniel Blain, chairman, Washington, D. C.; Dr. Paul E. Huston, Iowa City; Dr. Philip Q. Roche, Philadelphia, and Dr. Manfred S. Guttmacher, Baltimore.

Dr. Joseph P. Evans, Cincinnati, read a paper entitled "Acute Head Injury," which was discussed by Drs. E. Jefferson Browder, Brooklyn, and Robert A. Groff, Philadelphia.

A paper entitled "X-Ray Visualization of the Intervertbral Disc 'Discography,'" was presented by Drs. W. James Gardner, R. E. Wise, E. C. Weiford, and C. R. Hughes, Cleveland. This paper was discussed by Drs. Edward Chamberlain, Philadelphia; Frederick P. Moersch, Rochester, Minn.; Ralph B. Cloward, Honolulu, and Dr. Gardner.

Drs. E. A. Spiegel, H. T. Wycis, and Herbert Freed, Philadelphia, presented a paper entitled "Stereoencephalotomy (Thalamotomy and Related Procedures)." This paper was discussed by Drs. J. W. Papez, Columbus, Ohio; John Hunter, Montreal, Canada, and Dr. Spiegel.

Dr. H. Russell Meyers, Iowa City, read a paper entitled "The Surgical Treatment of Epilepsy: Remarks Concerning Current Premises and Criteria for Evaluation End Results," which was discussed by Dr. Herbert Jasper, Montreal, Canada; A. Earl Walker, Baltimore, and Dr. Meyers.

Dr. James W. Watts, Washington, D. C., read a paper entitled "Psychosurgery: Accomplishments, Limitations and Risks in the Management of Intractable Pain." This paper was discussed by Drs. Yale D. Koskoff, Pittsburgh, and Gilbert Horrax, Boston.

Dr. Michael M. Scott, Philadelphia, read a paper entitled "Cerebral Apoplexy Due to Intracranial Hemorrhage: The Life-Saving Value of Surgical Intervention." This paper was discussed by Drs. Lester A. Mount, New York; Stephen E. Gurdjian, Detroit; H. Russell Meyers, Iowa City, and Dr. Scott.

SECTION ON OBSTETRICS AND GYNECOLOGY

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr. Arthur B. Hunt, Rochester, Minn.

Dr. Clarence C. Briscoe, Philadelphia, read a paper on "The Use of Intravenous Iron in the Practice of Obstetrics and Gynecology," which was discussed by Dr. Harvey B. Matthews, Brooklyn.

Drs. Milton L. McCall and Harry W. Taylor, Philadelphia, presented a paper on "The Effect of Barbiturate Sedation on the Brain in Toxemia of Pregnancy." This paper was discussed by Dr. Thaddeus L. Montgomery, Philadelphia.

Drs. Henry B. Turner and Frank E. Whitacre, Memphis, Tenn., presented a paper on "Changes in the Treatment of Eclampsia," which was discussed by Drs. Charles H. Peckham, Manchester, Conn.; Thomas K. Preston, Anthony, N. M., and B. H. Passmore, San Antonio, Texas.

Drs. H. Bristol Nelson, Brookline, Mass., and Priscilla White, Boston, presented a paper on "The Management of Pregnancy in the Diabetic Patient." This paper was discussed by Drs. Samuel A. Cosgrove, Jersey City, N. J., and Priscilla White, Boston.

Drs. William Mulligan and John Rock, Brookline, Mass., presented a paper on "The Response of Human Ovaries to Hypophysial Gonadotropins." This paper was discussed by Drs. Elmer Louis Sevringhaus, Nutley, N. J., and M. Edward Davis, Chicago.

Dr. Robert J. Lowrie, New York, presented a paper on "Frigidity in Women," which was discussed by Drs. Sophia J. Kleegman and Anna Kleegman Daniels, New York.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. Louis H. Douglass, Baltimore; vice chairman, Dr. Albert W. Holman, Portland, Ore.; secretary, Dr. Bernard J. Hanley, Los Angeles; delegate, Dr. Harvey B. Matthews, Brooklyn; alternate delegate, Dr. Daniel G. Morton, Los Angeles; representative to the Scientific Exhibit, Dr. Frederick H. Falls, Chicago. Also elected were: representative to the Board of Governors of the American College of Surgeons, Dr. Willard R. Cooke, Galveston, Texas; representatives to the American Board of Obstetrics and Gynecology; Dr. F. Bayard Carter, Durham, N. C., Dr. Robert A. Kimbrough Jr., Philadelphia, and Dr. Robert L. Faulkner, Cleveland; representatives to the American Committee on Maternal Welfare, Dr. William Benbow Thompson, Los Angeles, Dr. Robert D. Mussey, Rochester, Minn., and Dr. Oren Moore, Charlotte, N. C.; representative to the Board of Governors of the National Federation of Obstetric-Gynecologic Societies, Dr. Ralph E. Campbell, Madison, Wis.

The section went on record at favoring the International Recommendations on Definitions of Live Birth and Fetal Death as presented in U. S. Public Health Service publication No. 39.

The section endorsed the new classification of cervical carcinoma as approved at the Fourth American Congress on Obstetrics and Gynecology, May 14-19, 1950.

On motion of Dr. Emil Novak, Baltimore, seconded by Dr. Alfred J. Kobak, Chicago, it was voted to adopt a resolution requesting the Board of Trustees to allocate additional funds to each section sufficient in amount to pay the expenses in full or in part of the section delegates to the American Medical Association sessions.

Dr. Arthur B. Hunt, Rochester, Minn., presented the chairman's address, entitled "Experiences with Test of Labor; Evaluation of Its Present Worth."

Dr. Albert Sharman, Glasgow, Scotland, presented a paper on "Some Therapeutic Experiments in Female Infertility."

Drs. Douglas M. Haynes, Dallas, Texas; W. W. Brown, Waco, Texas; Richard L. Hermes, Lawrence, Kans., and C. R. Bates Jr. and William F. Mengert, Dallas, Texas, presented a paper on "Cytology for Early Detection of Uterine Cancer." This paper was discussed by Drs. Charles E. Smith, Chicago; John R. Graham, Boston, and Sophia J. Kleegman, New York.

Drs. Gerald A. Galvin, Howard W. Jones and Richard W. TeLinde, Baltimore, presented a paper on "The Clinical Relationship Between Carcinoma in Situ and Invasive Carcinoma of the Cervix." This paper was discussed by Drs. James A. Corscaden, New York; Jacob Hoffman, Philadelphia; Charles S. Stevenson, Detroit; Emil Novak, Baltimore, and Carl Henry Davis, Miami, Fla.

Drs. Alfred J. Kobak, Charles Fields and James E. Fitzgerald, Chicago, presented a paper on "Chemo-Antibiotics and Low Cervical Cesarean Section in Dystocia or Intrapartum Sepsis." This paper was discussed by Drs. Gordon Douglas, New York; Arthur B. Hunt, Rochester, Minn.; J. Bay Jacobs, Washington, D. C., and Bernard J. Hanley, Los Angeles.

Dr. H. L. Stewart Jr. presented a paper on "The Duration of Pregnancy and Postmaturity," which was discussed by Dr. Allan C. Barnes, Columbus, Ohio.

FRIDAY, JUNE 15—MORNING

Drs. Richard Torpin and Alva M. H. Faulkner, Augusta, Ga., presented a paper on "Further Studies in Regard to the Influence of the Placental Site on Fetal Presentation." This paper was discussed by Dr. Charles S. Stevenson, Detroit.

Drs. George Schaefer, Forest Hills, N. Y., and Harry H. Epstein, Jamaica, N. Y., presented a paper on "Therapeutic Abortion in Pulmonary Tuberculosis," which was discussed by Dr. Edward W. Hayes, Monrovia, Calif.

Drs. Harry Sered, Frederick H. Falls and Bruce P. Zummo, Chicago, presented a paper on "Further Observations in the Management of Gynecologic Tuberculosis with Streptomycin." This paper was discussed by Dr. Paula M. Horn, Los Angeles, and Dr. Albert Sharman, Glasgow, Scotland.

Drs. W. H. Grimes, R. A. Bartholomew, E. D. Colvin, John S. Fish, and William M. Lester, Atlanta, Ga., presented a paper on "Management of Breech Presentation in Pregnancy and Labor." This paper was discussed by Drs. Milton G. Potter, Buffalo; Bernard J. Hanley, Los Angeles, and Frederick H. Falls, Chicago.

Drs. S. Leon Israel and Alfred S. Conston, Philadelphia, presented a paper on "Unrecognized Pituitary Necrosis (Sheehan's Syndrome): A Cause of Sudden Death." This paper was discussed by Dr. David N. Danforth, Evanston, Ill., and Dr. Arthur B. Hunt, Rochester, Minn.

Dr. Charles Newberger, Chicago, presented a paper on "Maternal Mortality in Downstate Illinois: A Three-Year Review, 1948-1950," which was discussed by Drs. Philip F. Williams, Philadelphia; Frederick H. Falls, Chicago, and Michael S. Rapp, Staten Island, N. Y.

COMBINED MEETING OF SECTION ON OPHTHALMOLOGY WITH ASSOCIATION FOR RESEARCH IN OPHTHALMOLOGY

Association for Research in Ophthalmology

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9:30 a. m. by the chairman of the Association for Research in Ophthalmology, Dr. Kenneth C. Swan, Portland, Ore.

Dr. Robert J. Masters, Indianapolis, chairman of the Section on Ophthalmology, expressed gratification on behalf of the section that the Association for Research in Ophthalmology had accepted the invitation of the section to meet with it.

Dr. K. W. Ascher, Cincinnati, read a paper on "Aqueous Veins and Contact Lenses," which was discussed by Drs. Georgiana Theobald, Oak Park, Ill.; Ludwig von Sallman, Joseph I. Pascal, and John M. McLean, New York, and K. W. Ascher, Cincinnati.

Drs. Gordon S. Christiansen and P. J. Leinfelder, Iowa City, presented a paper on "A Critical Study of Lens Metabolism: (1) Nonenzymatic 'Respiration'; (2) Glycolysis." This paper was discussed by Drs. John Harris, Washington, D. C.; John Bellows, Chicago; William Hart, Philadelphia; Jonas S. Friedenwald, Baltimore; V. Everett Kinsey, Detroit, and Gordon S. Christiansen, Iowa City.

Dr. Peter C. Kronfeld, Chicago, read a paper on "The Chemical Demonstration of Transconjunctival Passage of Aqueous After Antiglaucomatous Operations," which was discussed by Drs. Harold G. Scheie, Philadelphia, and Peter C. Kronfeld, Chicago.

Drs. Jay G. Linn Jr. and Raymond C. Tomarelli, Pittsburgh, presented a paper entitled "An Evaluation of the Various Anticholinesterase Agents." This paper was discussed by Drs. W. Morton Grant, Boston, and Jay G. Linn Jr., Pittsburgh.

WEDNESDAY, JUNE 13—AFTERNOON

Drs. M. L. Stillerman, E. L. Gibbs and Meyer Perlstein, Chicago, presented a paper on "Encephalographic Changes in Strabismus." This paper was discussed by Drs. George Guibor, Chicago; Donald Lyle, Cincinnati; Arthur Linksz, New York; Harold Falls, Ann Arbor, Mich., and M. L. Stillerman, Chicago.

Drs. Franklin P. Bousquet and William E. Laupus, New York, presented a paper on "Retrolental Fibroplasia: The Role of Hemorrhage in Its Pathogenesis," which was discussed by Drs. Frederick H. Verhoeff and Parker Heath, Boston; Harold Falls, Ann Arbor, Mich.; Jonas Friedenwald, Baltimore, and Franklin P. Bousquet, New York.

Dr. John W. Patterson, Cleveland, read a paper on "Diabetic Cataract Formation," which was discussed by Drs. Ludwig von Sallman, New York; David G. Cogan, Boston, and John W. Patterson, Cleveland.

Drs. Seymour P. Halbert and Lois Swick, New York, presented a paper on "Antibiotic-Producing Bacteria of the Ocular Flora." This paper was discussed by Drs. Henry F. Allen, Boston; Alson E. Braley, Iowa City, and Seymour P. Halbert, New York.

Dr. Joseph V. M. Ross, Berwick, Pa., read a paper on "Polymyxin in Experimental Ocular Pseudomonas Aeruginosa Infections."

Dr. Robert L. Wiggins, New York, read a paper on "Experimental Studies on the Eye with Polymyxin B."

These two papers were discussed by Drs. Henry F. Allen, Boston; Alson E. Braley, Iowa City, and Ludwig von Sallman, New York.

THURSDAY, JUNE 14—MORNING

Dr. Glenn O. Dayton Jr., Buffalo, read a paper on "The Effect of ACTH on Experimentally Produced Exophthalmus," which was discussed by Drs. Lorand V. Johnson, Cleveland; John M. McLean, New York; John W. Henderson, Rochester, Minn., and Glenn O. Dayton Jr., Buffalo.

Dr. Gordon L. Walls, Berkeley, Calif., read a paper on "The Lateral Geniculate Nucleus and Visual Histophysiology," which was discussed by Drs. Donald Lyle, Cincinnati; David G. Cogan, Boston; Jonas S. Friedenwald, Baltimore; Arthur Linksz, New York, and Gordon L. Walls, Berkeley, Calif.

Drs. Albert M. Potts and Lorand V. Johnson, with the technical assistance of Doris Goodman, Cleveland, presented a paper on "Studies on the Visual Toxicity of Methyl Alcohol: The Effect of Methyl Alcohol and Its Oxidation Products on Some Retinal Metabolic Processes."

Drs. Anita P. Gilger, Albert M. Potts and Lorand V. Johnson, Cleveland, presented a paper on "Studies on the Visual Toxicity of Methyl Alcohol: The Effect of Parenterally Administered Substances on the Systemic Toxicity of Methyl Alcohol."

These two papers were discussed by Drs. Virgil G. Casten, Boston; P. J. Leinfelder, Iowa City; Jonas S. Friedenwald, Baltimore; David G. Cogan, Boston; Gordon L. Walls, Berkeley, Calif.; Walter H. Fink, Minneapolis, and Albert M. Potts and Anita P. Gilger, Cleveland.

Dr. Warner K. Noell, Randolph Field, Texas, read a paper on "Electrophysiological Study of the Retina During Metabolic Impairment," which was discussed by Drs. J. E. Lebensohn, Chicago, and William J. Holmes, Honolulu.

Drs. C. G. Smith and C. D. Baird, Toronto, Canada, presented a paper on "The Effect of Experimental Ischemia on the Retinal Cells Due to Intraocular-Pressure Increase." This paper was discussed by Drs. Derrick Vail, Chicago; P. Robb McDonald, Philadelphia; A. Alexander Knapp, New York; Henri Pichette, Quebec City, Canada, and C. G. Smith, Toronto, Canada.

Section on Ophthalmology

THURSDAY, JUNE 14—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr. Robert J. Masters, Indianapolis.

The chairman announced with regret that Dr. Holger Ehlers, Copenhagen, Denmark, would be unable to attend the meeting due to pressure of duties at home. He presented two foreign guests, Dr. Antonio Grignolo, Parma, Italy, and Dr. Florian Verrey, Zurich, Switzerland.

Dr. M. Hayward Post, St. Louis, chairman of the executive committee of the section, presented the Prize in Ophthalmology to Dr. Georgiana Dvorak Theobald, Chicago.

The chairman's address was read by Dr. Robert J. Masters, Indianapolis.

Dr. W. Morton Grant, Boston, read a paper on "Clinical Measurements of Aqueous Outflow," which was discussed by Drs. Jonas S. Friedenwald, Baltimore; Paul A. Chandler, Boston; Peter C. Kronfeld, Chicago; K. W. Ascher, Cincinnati, and Thomas M. D'Angelo, Flushing, New York.

Drs. Solomon S. Brav and H. Peter Kirber, Philadelphia, presented a paper on "Mass Screening for Glaucoma." This paper was discussed by Drs. Peter C. Kronfeld, Chicago; Adolph Posner, New York; H. Saul Sugar, Detroit; Franklin M. Foote, New York; Louis Lehrfeld, Philadelphia; Harold P. Falls, Ann Arbor, Mich.; K. W. Ascher, Cincinnati, and Solomon S. Brav, Philadelphia.

The chairman, Dr. Robert J. Masters, Indianapolis, read a communication from Dr. George F. Lull, Secretary of the American Medical Association, regarding the American Medical Education Foundation.

Dr. Everett L. Goar, Houston, Texas, read a paper on "Rheumatoid Nodules of the Eye," which was discussed by Drs. Frederick H. Verhoeff, Boston; Merrill J. King, Brookline, Mass.; A. Alexander Knapp, New York, and Everett L. Goar, Houston, Texas.

Dr. Arthur A. Siniscal, Rolla, Mo., read a paper on "Sulfonamides and Antibiotics in Trachoma," which was discussed by Drs. Alson E. Braley, Iowa City; Henry F. Allen, Boston; Frederick H. Theodore, New York, and Arthur A. Siniscal, Rolla, Mo.

Dr. Florian Verrey, Zurich, Switzerland, presented a film on "The Cytology of the Aqueous Humor."

FRIDAY, JUNE 15—MORNING

EXECUTIVE SESSION

The Executive Session was called to order at 9 o'clock by the chairman, Dr. Robert J. Masters, Indianapolis.

The secretary, Dr. Trygve Gundersen, Boston, read the report of the American Committee on Optics and Visual Physiology, which was accepted and filed, on motion duly seconded and carried.

Dr. Algernon B. Reese, chairman, read the report of the Committee for the Award of the Knapp Medal for the Year 1950. On motion of Dr. Everett L. Goar, seconded by Dr. Parker Heath and carried, the report was received and filed.

In the absence of the chairman, Dr. Phillips Thygeson, Dr. Gundersen read the report of the Committee on the American Board of Ophthalmology. There being no objection, the report was received and filed.

Dr. Parker Heath, consultant, read the Report of the Registry of Ophthalmic Pathology. Without objection, the report was received and filed.

Dr. Gundersen read the report of the Exhibit Committee, of which Dr. Georgiana D. Theobald is chairman. There being no objection, the report was received and filed.

Dr. Gundersen read the report of the Committee on Museum of Ophthalmic History. Without objection, the report was received and filed.

Dr. Parker Heath read the report on the Knapp Testimonial Fund. Dr. Arthur Bedell moved that the Section on Ophthalmology record its thanks to the Kresge Foundation for its generous contribution. The motion was duly seconded and carried.

Dr. M. Hayward Post, delegate to the 16th International Congress of Ophthalmology, read his report. At the conclusion of the report, Dr. Post gave special recognition to the great service that Dr. Bernard Samuels has done for American ophthalmology in bringing the next International Congress to this country. Without objection, Dr. Post's report was received and filed.

Dr. Post moved that the executive committee be empowered to contact Prof. Eduoard Hart of Paris with an application by the section for membership in the International Federation of Ophthalmological Societies. The motion was seconded by Dr. Everett L. Goar and carried.

The report of Dr. A. D. Ruedemann, chairman of the Joint Committee on Industrial Ophthalmology of the American Medical Association and the American Academy of Ophthalmology and Otolaryngology, was received and filed.

Dr. Post read the report of the executive committee, which was received. In receiving the report, the section elected the officers nominated by the committee, as follows: chairman, Dr. Edwin B. Dunphy, Boston; vice chairman, Dr. Georgiana Dvorak Theobald, Oak Park, Ill.; secretary, Dr. Trygve Gundersen, Boston; delegate, Dr. William L. Benedict, Rochester, Minn.; alternate delegate, Dr. Harvey E. Thorpe, Pittsburgh.

In connection with the announcement of an invitation to attend a meeting of the Viennese Ophthalmological Society honoring the one hundredth anniversary of the birth of Prof. Ernst Fuchs, Dr. Dorman Pischel, San Francisco, offered the following resolution which was unanimously adopted:

> WHEREAS, The visit to the United States in 1921 by Prof. Ernst Fuchs was a great stimulus to the further development of ophthalmology in this country; and
>
> WHEREAS, Many of the members of this Section had an opportunity to meet this distinguished ophthalmologist whom they now remember with great respect and affection; and
>
> WHEREAS, All ophthalmologists in the United States appreciate the great and lasting contributions to ophthalmology made by him; therefore be it
>
> *Resolved,* That the Section on Ophthalmology of the American Medical Association send its greetings and best wishes to the Viennese Ophthalmological Society on the occasion of its celebration in honor of the one hundredth anniversary of the birth of Ernst Fuchs; and be it further
>
> *Resolved,* That this Section wishes to join with the Viennese Ophthalmological Society in paying respect to the memory of the illustrious Professor Ernst Fuchs.

On nominations made from the floor, the following were elected as the Committee for the Award of the Knapp Medal for 1951: Dr. Frederick A. Davis, Madison, Wis.; Dr. John H. Dunnington, New York, and Dr. Arthur J. Bedell, Albany, N. Y.

SCIENTIFIC SESSION

Dr. Charles L. Schepens, Boston, read a paper on "Subclinical Retinal Detachment," which was discussed by Drs. John H. Dunnington, New York; P. Robb McDonald, Philadelphia; S. Rodman Irvine, Baltimore; Harvey E. Thorpe, Pittsburgh; Henry Minsky, New York; Jonas S. Friedenwald, Baltimore; Florian Verrey, Zurich, Switzerland, and Charles L. Schepens, Boston.

Dr. Antonio Grignolo, Parma, Italy, read a paper on "Fibrous Components of the Vitreous Body." This paper was discussed by Drs. Ludwig von Sallman, New York; Jonas S. Friedenwald, Baltimore; Harvey E. Thorpe, Pittsburgh; Henry Minsky, New York, and Antonio Grignolo, Parma, Italy.

Dr. Alston Callahan, Birmingham, Ala., read a paper on "Lateral Cataract Extraction Following Filtering Operation," which was discussed by Drs. Frederick H. Verhoeff, Boston; Everett L. Goar, Houston, Texas; A. Alexander Knapp, New York; Samuel J. Meyer, Chicago, and Alston Callahan, Birmingham, Ala.

FRIDAY, JUNE 15—AFTERNOON

Dr. Walter H. Fink, Minneapolis, read a paper on "The Vertical Component in Strabismus," which was discussed by Drs. Francis H. Adler, Philadelphia; Lorand V. Johnson, Cleveland, and Walter H. Fink, Minneapolis.

Dr. Harvey E. Thorpe, Pittsburgh, read a paper on "ACTH and Cortisone in Ocular Surgery," which was discussed by Drs. R. Townley Paton and John M. McLean, New York, and Harvey E. Thorpe, Pittsburgh.

Drs. Algernon B. Reese, Frederick C. Blodi, William A. Silverman and John C. Locke, New York, presented a paper on "The Influence of ACTH on the Course of Retrolental Fibroplasia." This paper was discussed by Drs. Victor Everett Kinsey, Detroit; William C. Owens, Baltimore; Merrill J. King, Boston, and Algernon B. Reese, New York.

Dr. Irwin T. Mancall, Boston, read a paper on "Occlusion of the Central Retinal Vein," which was discussed by Drs. Angus L. MacLean, Baltimore, and Frederick H. Verhoeff, Boston.

Drs. Ivan F. Duff, Harold F. Falls and James W. Linman, Ann Arbor, Mich., presented a paper on "Anticoagulant Therapy in Occlusive Vascular Retinal Disease." This paper was discussed by Drs. Alexander E. MacDonald, Toronto, Canada; Irving H. Leopold, Philadelphia, and Harold F. Falls, Ann Arbor, Mich.

Drs. George M. Haik, Wood Lyda and Richey L. Waugh Jr., New Orleans, presented a paper on "Sympathetic Ophthalmia." This paper was discussed by Drs. Alan C. Woods, Baltimore; Paul A. Chandler, Boston; S. Rodman Irvine, Baltimore; Daniel M. Gordon, New York, and Wood Lyda, New Orleans.

SECTION ON ORTHOPEDIC SURGERY

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr. Walter P. Blount, Milwaukee.

The chairman announced that because of the absence of Dr. Joseph S. Barr, Boston, he had appointed the vice chairman, Dr. Frederic C. Bost, San Francisco, to serve on the executive committee.

Dr. Frank G. Murphy, Chicago, read a paper on "Complications of Nonunion of Fractures with Modern Treatment," which was discussed by Drs. George O. Eaton, Baltimore; Richard T. Hudson, Louisville, Ky., and Frank G. Murphy, Chicago.

Drs. George J. Garceau and Eugene Salvati, Indianapolis, presented a paper on "Complications of Orthopedic Surgical Procedures." This paper was discussed by Drs. I. William Nachlas, Baltimore; Frederick R. Thompson, New York, and George J. Garceau, Indianapolis.

Dr. Julius S. Neviaser, Washington, D. C., read a paper on "Acromioclavicular Dislocation Treated by Transference of the Coracoacromial Ligament," which was discussed by Drs. Andrew Schildhaus, Brooklyn, and August W. Spittler and Julius S. Neviaser, Washington, D. C.

Dr. Jesse T. Nicholson, Philadelphia, read a paper on "Glenoid Shelf Operation for Recurrent Dislocation of the Shoulder," which was discussed by Drs. Frederic C. Bost, San Francisco; J. Hamilton Allan, Charlottesville, Va., and Jesse T. Nicholson, Philadelphia.

Dr. Moore Moore Jr., Memphis, Tenn., read a paper on "Radiohumeral Synovitis," which was discussed by Drs. Milton C. Cobey, Washington, D. C.; Donald C. Conzett, Dubuque, Iowa, and Walter P. Blount, Milwaukee.

Dr. Henry Herman Young, Rochester, Minn., read a paper on "Nonneurologic Lesions Simulating Protruded Intervertebral Disk." This paper was discussed by Drs. David M. Bosworth, New York; Robert J. Joplin, Brookline, Mass., and Henry Herman Young, Rochester, Minn.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. Frederic C. Bost, San Francisco; vice chairman, Dr. Henry R. McCarroll, St. Louis; representatives to the American Board of Orthopedic Surgery, Mather Cleveland, New York, and Walter Graham, Santa Barbara, Calif; chairman, section committee on Scientific Exhibits, Dr. J. Vernon Luck, Los Angeles; delegate, Dr. Edward L. Compere, Chicago; alternate, Dr. Francis M. McKeever, Los Angeles.

Drs. F. P. Kreuz, G. W. Hyatt, T. C. Turner and C. A. L. Bassett, Bethesda, Md., presented a paper on "The Use of Preserved Tissues in Orthopedic Surgery." This paper was discussed by Drs. Philip D. Wilson, New York; Lenox D. Baker, Durham, N. C., and G. W. Hyatt, Bethesda, Md.

As a variation from the usual procedure, the author listed and the two discussants combined in writing a paper on "Medullary Fixation of the Femur: Indications, Technic, Complications and Errors," which was presented in succession by Drs. Edwin F. Cave, Boston; August W. Spittler, Washington, D. C. and Hugh M. A. Smith, Memphis, Tenn.

Dr. Edward L. Compere, Chicago, as the delegate of the section, reported extemporaneously on the work of the House of Delegates.

Dr. Henry R. McCarroll, St. Louis, moved that the Section on Orthopedic Surgery go on record as requesting the Board of Trustees of the American Medical Association to appropriate a sum of money to the section, of not less than $1500, for the section to use as it sees fit in defraying the necessary expenses of the section delegate to the House of Delegates. The motion was seconded by Dr. Samuel Kleinberg, New York, and carried.

Dr. Samuel Kleinberg, New York, moved that the section pass a resolution requesting that the By-Laws of the American Medical Association be amended to make the delegate of the section a member of the executive committee of the Section on Orthopedic Surgery. The motion was seconded by Dr. H. H. Young, Rochester, Minn., and carried unanimously.

Dr. Walter P. Blount, Milwaukee, read the chairman's address on "Control of Bone Length."

Drs. John G. Kuhns, Boston, and Robert S. Hormell, Brookline, Mass., presented a paper on "Congenital Scoliosis." This paper was discussed by Drs. Samuel Kleinberg, New York; Walter P. Blount, Milwaukee, and John G. Kuhns, Boston.

Dr. Jack K. Wickstrom, New Orleans, read a paper on "Rehabilitation of Civilian Amputees: An Evaluation of 235 Amputees and the Problems of Their Rehabilitation." This paper was discussed by Drs. T. Campbell Thompson, New York; Henry H. Kessler, Newark, N. J., and Jack K. Wickstrom, New Orleans.

FRIDAY, JUNE 15—MORNING

Dr. Leonard T. Peterson, Washington, D. C., read a paper on "Principles of Internal Fixation with Plates and Screws," which was discussed by Drs. Francis W. Glenn, Miami, Fla.; Vernon P. Thompson, Los Angeles; Elmer P. Weigel, Plainfield, N. J., and Leonard T. Peterson, Washington, D. C.

Drs. Maurice M. Pike and J. Whitfield Larrabee, Hartford, Conn., presented a paper on "The Use of Cancellous Bone Grafts in Those Fresh Fractures Which Come to Open Reduction." This paper was discussed by Drs. William J. Tobin, Washington, D. C. and Maurice M. Pike, Hartford, Conn.

Dr. Dana M. Street, Memphis, Tenn., read a paper on "Medullary Fixation in the Forearm," which was discussed by Drs. Donald T. Imrie, Vicksburg, Miss.; Henry R. McCarroll, St. Louis; Richard T. Hudson, Louisville, Ky., and Dana M. Street, Memphis, Tenn.

Drs. Carl E. Badgley and Sylvester J. O'Connor, Ann Arbor, Mich., presented a paper on "Conservative Treatment of Tibial Plateau Fractures." This paper was discussed by Drs. John R. Moore, Philadelphia; John T. Jacobs, Denver; David M. Bosworth, New York, and Sylvester J. O'Connor, Ann Arbor, Mich.

Drs. Rudolph S. Reich and Norman J. Rosenberg, Cleveland, presented a paper on "Fractures of the Patella." This paper was discussed by Drs. Luther M. Strayer Jr., Bridgeport, Conn.; J. Neill Garber, Indianapolis, and Norman J. Rosenberg, Cleveland.

Drs. William T. Green and Jonathan Cohen, Boston, presented a paper on "Osteoid Osteoma in Children." This paper was discussed by Drs. Edward L. Compere, Chicago; Robert B. Portis, Beverly Hills, Calif., and William T. Green, Boston.

SECTION ON PATHOLOGY AND PHYSIOLOGY

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9:10 a. m. by the chairman, Dr. Stanley P. Reimann, Philadelphia.

Dr. Carl J. Wiggins, Cleveland, read a paper entitled "The Regulation of Cardiac Performance: Facts vs. Theories," which was discussed by Drs. George E. Wakerlin, Chicago, and Robert W. Wilkins, Boston.

A paper entitled "Modern Concepts of Acid-Base Regulation" was read by Dr. Robert F. Pitts, Syracuse, N. Y., and was discussed by Drs. Campbell Moses, Pittsburgh, and William S. Hoffmann, Chicago.

Dr. Jesse P. Greenstein, Bethesda, Md., presented a paper on "Effect of Cancer on Liver Enzymes." This paper was discussed by Dr. Jacob Taub, New York.

A paper entitled "Tissue Reactions to a Bacterial Polysaccharide Used in the Chemotherapy of Malignant Tumors" was presented by Dr. Andrew J. Donnelly, Philadelphia, and was discussed by Drs. Herbert S. Bowman, Philadelphia; George E. Wakerlin, Chicago, and Jesse P. Greenstein, Bethesda, Md.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. Paul R. Cannon, Chicago; vice chairman, Dr. Lall G. Montgomery, Muncie, Ind.; secretary, Dr. Edwin F. Hirsch, Chicago; representative to Scientific Exhibit, Dr. Frank B. Queen, Portland, Ore.; representatives to American Board of Pathology, Drs. John Rudolf Schenken, Omaha, and Shields Warren, Boston.

The chairman, Dr. Stanley P. Reimann, Philadelphia, presented the chairman's address.

Dr. George E. Wakerlin, Chicago, read a paper entitled "The Kidney and Hypertension," which was discussed by Dr. Louis N. Katz, Chicago, and Drs. Stanley E. Bradley, Benjamin Jablons, Frederick M. Allen and Sidney A. Gladstone, New York.

A paper by Drs. Campbell Moses, Grace L. Rhodes, Evelyn Leatham and Robert S. George, Pittsburgh, entitled "The Effects of Cholesterol Feeding During Pregnancy on Blood Cholesterol, the Lipid Content of the Placenta and Placental Vascular Lesions" was presented, and was discussed by Drs. Ancel Keys, Minneapolis; Charles F. Wilkinson Jr., New York; Harry J. Corper, Denver; Laurance W. Kinsell, Oakland, Calif., and Campbell Moses, Pittsburgh.

Drs. Jacob Gershon-Cohen and Helen Ingleby, Philadelphia, presented a paper entitled "Comparative Radiology and Pathology of the Breast." This paper was discussed by Drs. Ernest E. Aegerter and Harold Isard, Philadelphia.

A paper entitled "A Study of the Mitochondria and Golgi Material in Neoplasms Arising in Human Tissues" by Drs. A. E. Bothe, A. J. Dalton and F. O. Zillessen, Philadelphia, was read, and was discussed by Dr. Harold Stewart, Bethesda, Md.

FRIDAY, JUNE 15—MORNING

Joint Meeting with Section on Gastro-Enterology and Proctology

Dr. Lester R. Dragstedt, Chicago, read a paper entitled "The Physiology of Gastric Secretion and Its Relation to the Ulcer Problem," which was discussed by Dr. George Crile Jr., Cleveland.

Dr. Richard B. Capps, Chicago, presented a paper on "Epidemiology of Acute Hepatitis." This paper was discussed by Drs. John R. Neefe, Philadelphia; Hyman I. Goldstein, Camden, N. J., and Richard B. Capps, Chicago.

A paper entitled "ACTH in Chronic Ulcerative Colitis: Clinical Observations," was presented by Dr. Joseph B. Kirsner, Chicago, and was discussed by Drs. J. Arnold Bargen, Rochester, Minn.; Walter L. Palmer, Chicago; Dr. Hyman I. Goldstein, Camden, N. J., and Joseph B. Kirsner, Chicago.

Dr. Yale Kneeland Jr., New York, presented a paper on "Antibiotics in Gastrointestinal Disorders." This paper was discussed by Dr. Z. T. Bercovitz, New York.

SECTION ON PEDIATRICS

WEDNESDAY, JUNE 13—AFTERNOON

The meeting was called to order at 2 o'clock by the chairman, Dr. Joseph B. Bilderback, Portland, Ore.

A panel discussion on The Therapy of Infectious Diseases was held, during which Dr. Waldo E. Nelson, Philadelphia, presided, and the following papers were presented:

Dr. Russell J. Blattner, Houston, Texas, read a paper on "Clinical Aspects of Host-Parasite Relationship."

Dr. Richard G. Hodges, Cleveland, read a paper on "Epidemiology of Upper Respiratory Diseases."

Dr. Waldo E. Nelson, Philadelphia, read a paper on "Clinical Bases for Selection of Patients for Antimicrobial Therapy."

Dr. Earle H. Spaulding, Philadelphia, read a paper on "Selection of Antimicrobial Agents by Laboratory Means."

The panel discussion was followed by a question and answer period, in which questions were presented from the floor, in written form, and were answered by the members of the panel.

THURSDAY, JUNE 14—AFTERNOON

The following officers were elected: chairman, Dr. Walter B. Stewart, Atlantic City, N. J.; vice chairman, Dr. Eugene T. McEnery, Chicago; secretary, Dr. Wyman C. C. Cole, Detroit; delegate, Dr. Woodruff L. Crawford, Rockford, Ill.; alternate delegate, Dr. Oliver L. Stringfield, Stamford, Conn.; alternate delegate to fill unexpired term of Dr. Julius Hess, now delegate because of resignation of Dr. William Weston Sr., Dr. Woodruff L. Crawford, Rockford, Ill.; custodian of the Abraham Jacobi Fund, Dr. Hugh L. Dwyer, Kansas City, Mo.; representative to Scientific Exhibit, Dr. F. Thomas Mitchell, Memphis, Tenn.

Dr. Hugh L. Dwyer, Kansas City, Mo., read the report on the Abraham Jacobi Fund.

The secretary, Dr. Wyman C. C. Cole, Detroit, announced that the preceding day the executive committee had authorized the Abraham Jacobi Fund to pay traveling expenses plus a $15 per diem to the delegate to the House of Delegates and also to the representative to the Scientific Exhibit.

The executive committee further directed that annual solicitation for contributions to the Abraham Jacobi Fund be made to the members and friends of the Section on Pediatrics, which was authorized by vote of the section at the Atlantic City session in 1949.

The following resolution was presented by Dr. F. Thomas Mitchell, Memphis, Tenn.:

> WHEREAS, It has been learned by the Section on Pediatrics of the American Medical Association in session at Atlantic City, N. J., June 13, 1951, that Dr. Alfred A. Walker is confined to his home because of serious illness, the membership wishes to convey to him the following resolution:
>
> *Resolved,* That those present in attendance at this meeting of the section wish to express their appreciation to him for his fellowship, friendship and long service and efficient capacity in the section, and wish him well in his present illness.

On motion of Dr. Mitchell, seconded by Dr. Margaret Mary Nicholson, Washington, D. C., the resolution was adopted.

Dr. James B. Stone, Richmond, Va., presented the following resolution:

> WHEREAS, Dr. William Weston Sr. has submitted his resignation as delegate from the section to the House of Delegates of the American Medical Association, after having filled this office faithfully and ably for over fifteen years; and
>
> WHEREAS, Both as a member of this section and as its former chairman, as well as its representative to the House of Delegates, his counsel has always been wise and constructive; and
>
> WHEREAS, During these years he has labored diligently and unceasingly to uphold the highest standards of the medical profession, has given many hours of hard work as well as utilized his unusual fount of knowledge, tact and experience for the betterment of pediatrics; and
>
> WHEREAS, His unfailing courtesy and his delightful sense of humor have made the path easier for many, as well as making himself honored and beloved by all who have had the privilege of knowing him; therefore be it
>
> *Resolved,* That the Section on Pediatrics now record its deep regret at his resignation and express its high esteem of him, and its deep appreciation of the services of this Christian gentleman.

On motion of Dr. Stone, seconded by Dr. Margaret Mary Nicholson, Washington, D. C., the resolution was adopted.

Dr. Margaret Mary Nicholson, Washington, D. C., presented the following resolution:

> WHEREAS, The past years have been fraught with danger from the activities of those persons who would replace voluntary medicine with politically controlled medicine; and
>
> WHEREAS, Those activities have been held in abeyance by the diligence, foresight and leadership of our President, Dr. Elmer L. Henderson; therefore be it
>
> *Resolved,* That the Section on Pediatrics now record its grateful appreciation of his outstanding work during the past year, which has been eminently successful.

On motion regularly made and seconded, the resolution was adopted.

Dr. Joseph B. Bilderback, Portland, Ore., read the chairman's address.

Drs. Tom D. Spies, Samuel Dreizen, George S. Parker and Donald J. Silberman, Birmingham, Ala., presented a paper on "Recent Observations in the Detection and Treatment of Nutritive Failure in Children." This paper was discussed by Dr. Arild E. Hansen, Galveston, Texas.

Drs. Werner Henle and Gertrude Henle, Philadelphia, presented a paper on "The Prevention of Mumps," which was discussed by Dr. Joseph Stokes Jr., Philadelphia.

Dr. Aims C. McGuinness, Philadelphia, read a paper on "A Review of Current Trends in Active and Passive Immunization," which was discussed by Drs. L. W. Sauer, Evanston, Ill.; James P. Leake, Washington, D. C., and Joseph Stokes Jr., Philadelphia.

Dr. Vida H. Gordon, Little Rock, Ark., read a paper on "Infantile Eczema: Management in Pediatric Practice and Prophylactic Measures for Control of Future Allergic Disease."

Dr. Jerome Glaser, Rochester, N. Y., read a paper on "The Use of ACTH and Cortisone in the Treatment of Bronchial Asthma and Eczema in Pediatric Practice."

Drs. Leon Unger, Albert H. Unger and A. Alvin Wolf, Chicago, presented a paper on "The Treatment and Results of Treatment of Bronchial Asthma in Children."

These three papers were discussed by Drs. George L. Waldbott, Detroit; Theron G. Randolph, Chicago; Morton Zall, Los Angeles, and M. Murray Peshkin, New York.

FRIDAY, JUNE 15—AFTERNOON

Dr. Jay M. Arena, Durham, N. C., read a paper on "Household Poisoning in Children."

Dr. Philip M. Stimson, New York, read a paper on "Treatment of Acute Poliomyelitis," which was discussed by Dr. Horace L. Hodes, New York.

Dr. Arild E. Hansen, Galveston, Texas, read a paper on "The New Challenge for Early Diagnosis in Acute Rheumatic Fever." This paper was discussed by Drs. William Weston Jr., Columbia, S. C., and George M. Wheatley, New York.

Dr. Samuel Livingston, Baltimore, read a paper on "The Medical Management of Epilepsy," which was discussed by Dr. H. M. Keith, Rochester, Minn.

Drs. Charles U. Lowe and Charles D. May, Minneapolis, presented a paper on "The Treatment of Chronic Idiopathic Intestinal Insufficiency (Celiac Disease)." This paper was discussed by Drs. L. Emmett Holt Jr., and Merrill P. Haas, New York, and Charles U. Lowe, Minneapolis.

Dr. Walter Finke, Rochester, N. Y., read a paper on "Childhood Pneumonia: A Common Cause of Bronchopulmonary Disease," which was discussed by Dr. Camille D. Cayley, New York.

SECTION ON PHYSICAL MEDICINE AND REHABILITATION

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9:15 a. m. by the chairman, Dr. George Morris Piersol, Philadelphia.

A paper entitled "Treatment of Some Complications of Colles' Fracture" was presented by Drs. Miland E. Knapp and Myron D. Lecklitner, Minneapolis.

Dr. Jessie Wright, Pittsburgh, read a paper on "Protective Body Mechanics in Arthritis," which was discussed by Dr. Edward E. Gordon, New York.

A paper on "Physical Medicine Plus Cortisone for Rheumatoid Arthritis,"was presented by Drs. Gordon M. Martin, Howard F. Polley and Thomas P. Anderson, Rochester, Minn., and was discussed by Dr. Walter M. Solomon, Cleveland.

Drs. Edward E. Gordon and Karl E. Carlson, New York, presented a paper on "Changing Attitudes Toward Multiple Sclerosis: A Program of Management." This paper was discussed by Drs. Howard A. Rusk, New York, and Frank H. Clark, Cleveland.

A paper on "Physical Medicine and Rehabilitation: Dynamic Therapy in Chronic Illness," was read by Dr. A. B. C. Knudson, Washington, D. C., and was discussed by Dr. Sydney S. Norwick, San Francisco.

Dr. Daniel Dancik, Northport, N. Y., read a paper on "Physical Medicine and Rehabilitation: Its Contribution and Role in a Large Psychiatric Hospital."

THURSDAY, JUNE 14—MORNING

Dr. George Morris Piersol, Philadelphia, read the chairman's address, entitled "The Present Obligation of Physical Medicine and Rehabilitation."

Dr. William Bierman, New York, read a paper on "Bell's Palsy," which was discussed by Drs. Sedgwick Mead, St. Louis; Ferdinand F. Schwartz, Birmingham, Ala.; Samuel Feuer, Brooklyn; Samuel J. Rosen, Pittsburgh; Frank R. Ober, Boston, and Madge C. McGuinness, New York.

Drs. John H. Kuitert and Raoul C. Psaki, Washington, D. C., presented a paper on "Common Diseases and Disabilities of the Hand," which was discussed by Dr. Herman Baezy, Dayton, Ohio.

Dr. Donald L. Rose, Kansas City, Kans., read a paper on "Rehabilitation of Hand Function in Rheumatoid Arthritis."

Dr. H. Worley Kendell, Chicago, presented a paper on "The Prevention and Correction of Deformities in Rheumatoid Arthritis with Assistive Devices."

The last two papers were discussed by Drs. David H. Kling, Los Angeles; Madge C. McGuinness, New York, and Frank H. Clark, Cleveland.

FRIDAY, JUNE 15—MORNING

Dr. Arthur L. Watkins, Boston, read a paper entitled "Practical Applications of Progressive Resistance Exercises."

Dr. Herman Schwan, Philadelphia, read a paper entitled "Limitations of Ultrasonics in Medicine."

Dr. M. A. Perlstein, Chicago, read a paper entitled "Some Clinical Aspects of Cerebral Palsy."

Dr. Henry H. Kessler, Newark, N. J., read a paper entitled "Rehabilitation of the Amputee."

Dr. Robert L. Bennett, Warm Springs, Ga., read a paper entitled "Functional Apparatus for Severely Weakened Upper Extremities."

A paper entitled "Bracing of Soft Tissue Disabilities of the Upper Extremity" was presented by Drs. Charles D. Shields and E. M. Smith, Washington, D. C., and was discussed by Drs. Gerald G. Hirschberg, New York, and Charles D. Shields, Washington, D. C.

SECTION ON PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9 o'clock by the chairman, Dr. Rutherford T. Johnstone, Los Angeles.

Dr. Rutherford T. Johnstone read his chairman's address entitled "Medicine: A Critique with No Tongue in Cheek."

The following papers were read as a symposium on "Occupational Health of Medical Personnel":

"Laboratory Infections," by Dr. S. Edward Sulkin, Dallas, Texas.

"Tuberculosis in Nurses and Medical Students," by Dr. H. D. Lees, Philadelphia.

"Professional Dermatitis," by Dr. Ervin H. Epstein, Oakland, Calif.

"Occupational Diseases of Dentists," by Dr. F. J. Orland, Chicago.

"Radiation Exposure in Atomic Medicine Nursing," by Dr. Marshall H. Brucer, Oak Ridge, Tenn.

"Diseases Acquired by Veterinary Surgeons," by Dr. R. C. Klussendorf, Terre Haute, Ind.

These six papers were discussed by Drs. Louis I. Dublin, New York, and Seward E. Miller, Washington, D. C.

THURSDAY, JUNE 14—MORNING

The following papers were read as a symposium on "Aging":

"Orientation in Problems of Aging," by Dr. Robert A. Moore, St. Louis.

"Psychiatric Aspects of Aging," by Dr. Leonard E. Himler, Ann Arbor, Mich.

"Public Health and Statistical Aspects of Aging," by Dr. Clarence J. Velz, Ann Arbor, Mich.

"Industrial Medical Aspects of Aging," by Dr. S. Charles Franco, New York.

"Sociological Aspects of Aging," by Miss Ollie A. Randall, New York.

"Training for Retirement of the Aged," by Dr. Phil N. Scheid, Chicago.

These six papers and remarks by Dr. Theodore G. Klumpp, moderator, were discussed by Drs. Harold W. Lovell, New

York; Clark Tibbitts, Washington, D. C.; O. L. Friedman, New York; I. J. Brightman, Albany, N. Y., and Daniel Blain, Washington, D. C.

Dr. Leon Pordy, New York, presented a paper on "The Value of Cardiac Function Tests in Industry." This paper was discussed by Dr. Morris E. Missal, Rochester, N. Y.; Dr. S. Charles Franco, New York, and Dr. Pordy.

The following officers were elected: chairman, Dr. Carey P. McCord, Detroit; vice chairman, Dr. Vlado A. Getting, Boston; secretary, Dr. Jean S. Felton, Oak Ridge, Tenn.; delegate, Dr. Rutherford T. Johnstone, Los Angeles; representative to Scientific Exhibit, Dr. Paul A. Davis, Akron, Ohio.

Friday, June 15—Morning

The following papers were read as a symposium on "A Critical Evaluation of Public Health Programs" with Dr. Herman E. Hilleboe, Albany, N. Y., as moderator:

"Venereal Disease Control," by Dr. John J. Wright, Chapel Hill, N. C.

"Nutrition," by Dr. Norman Jolliffe, New York.

"Tuberculosis Case Finding and Control," by Dr. W. C. Spring Jr., Ithaca, N. Y.

"Cancer Case Finding and Control," by Dr. N. E. McKinnon, Toronto, Canada.

"Responsibilities in Hospital Construction," by Dr. Robin C. Buerki, Philadelphia.

These papers were discussed by Drs. Theodore H. Noehren, Salt Lake City; Henry A. Holle, New York, and I. J. Brightman, Albany, N. Y.

SECTION ON RADIOLOGY

Wednesday, June 13—Afternoon

The meeting was called to order at 2 o'clock by the chairman, Dr. J. C. Dickinson, Tampa, Fla.

The secretary, Dr. Paul C. Hodges, Chicago, read the report of the delegate to the House of Delegates, embodying a resolution relative to the use of radium and radio-isotopes in hospitals. On motion regularly made and seconded, the resolution was adopted.

Dr. J. C. Dickinson, Tampa, Fla., read the chairman's address, "The General Practice of Radiology."

Dr. Ross Golden, New York, read a paper on "Functional Obstruction of the Efferent Loop of the Jejunum Following Partial Gastrectomy."

Drs. James F. Martin, Winston-Salem, N. C., and Hymer L. Friedell, Cleveland, presented a paper on "Partial Obstruction of the Small Bowel with Special Reference to the Obstructing Segment."

Drs. Everett L. Pirkey, Edsell S. Reed, William H. Smith and Gabriel Whiteman, Louisville, Ky., presented a paper on "The 'Profile Line' in the Differential Diagnosis of Intrinsic and Extrinsic Lesions of the Gastric Cardia."

Drs. Gladden V. Elliott and Hugh M. Wilson, St. Louis, presented a paper on "Mesenchymal Tumors of the Stomach."

Drs. Fred J. Hodges and Howard C. MacMillan, Ann Arbor, Mich., presented a paper on "Important Clinical Dividends from X-Ray Examinations of the Colon."

These papers were discussed by Drs. Fred J. Hodges, Ann Arbor, Mich.; Paul C. Swenson, Philadelphia, and Walter F. Gruber, New York.

Thursday, June 14—Afternoon

The following officers were elected: chairman, Dr. Ira H. Lockwood, Kansas City, Mo.; vice chairman, Dr. Paul C. Hodges, Chicago; secretary, Dr. Traian Leucutia, Detroit; representative to the Scientific Exhibit, Dr. Richard H. Chamberlain, Philadelphia.

Drs. C. F. Behrens, D. P. Jackson, E. P. Cronkite and J. G. Jacobs, Bethesda, Md., presented a paper on "Evaluation of the Platelet Role in the Hemorrhagic Phase of Radiation Injury."

Dr. Milton Friedman, New York, read a paper on "Seminoma of the Testis."

Dr. William Harris, New York, read a paper on "Use of a Grid in Roentgen Therapy for Advanced Cancer."

Drs. Ira I. Kaplan and Leslie L. Allen, New York, presented a paper on "Hodgkin's Disease: A Review of 242 Cases Treated in the Bellevue Hospital Radiation Therapy Department."

Drs. Roger A. Harvey, John S. Laughlin, Hugh Garrison and John R. Anderson, Chicago, presented a paper on "Comparison of Dose Distribution in Patients Treated with X-Ray Beams of Widely Different Energies."

Dr. Leonard B. Goldman, Jackson Heights, N. Y., read a paper on "Use of Lipids to Enhance the Effect of Roentgen Therapy in the Treatment of Pain from Advanced Cancer."

These papers were discussed by Drs. Hirsch Marks, and William Harris, New York, and Lester M. Freedman, Pittsburgh.

Friday, June 15—Afternoon

Dr. Rieva Rosh, New York, read a paper on "Irradiation of Recurrent and Residual Carcinoma of the Cervix After a Total and Subtotal Hysterectomy."

Drs. William B. Seaman and Alfred Goldman, St. Louis, presented a paper on "Roentgenographic Aspects of Pulmonary Arteriovenous Fistulas."

Drs. Edwin L. Lame and Hon Chong Chang, Philadelphia, presented a paper on "Pubic and Ischial Necrosis Following Pelvic Operation (Osteitis Pubis)."

Drs. Wallace S. Tirman and Harry W. Banker, Bluffton, Ind., presented a paper on "Microradiography."

Drs. Israel Steinberg and Charles T. Dotter, New York, presented a paper on "Lung Cancer: Diagnostic and Prognostic Value of Angiocardiography."

Drs. Laurence L. Robbins and Edwin H. Land, Boston, presented a paper on "The Application of the Land Method of Film Processing in Roentgenography."

These papers were discussed by Drs. Fred J. Hodges, Ann Arbor, Mich.; Paul C. Hodges, Chicago; Oscar V. Batson, Philadelphia, and Laurence Miscall, New York.

SECTION ON SURGERY, GENERAL AND ABDOMINAL

Wednesday, June 13—Afternoon

The meeting was called to order at 2 o'clock by the chairman, Dr. I. S. Ravdin, Philadelphia.

Dr. William A. Altemeier, Cincinnati, presented a paper on "Enzymatic Debridement of Thermal Wounds," which was discussed by Drs. Edwin J. Pulaski, San Antonio, Texas, and Louis M. Rousselot, New York.

Drs. Raymond M. Curtis, John H. Brewer and Ira W. Rose Jr., Baltimore, presented a paper on "A New Technic for the Local Treatment of Burns." This paper was discussed by Drs. Walter E. Fleischer and Harvey B. Stone, Baltimore; Irving L. Ochs, Annapolis, Md.; Paul E. Spangler, Portsmouth, Va., and Frederick M. Allen, New York.

Dr. James Barrett Brown, St. Louis, presented a paper on "Rehabilitation of Patients with Deep Burns," which was discussed by Dr. Herbert Conway, New York.

Drs. Joseph M. Miller, Perrin H. Long and Edward S. Stafford, Baltimore, presented a paper on "Streptokinase and Streptodornase in the Treatment of Infected Wounds." This paper was discussed by Drs. W. Ross McCarty and Frank B. Berry, New York; Michael E. DeBakey, Houston, Texas, and Otto C. Brantigan, Baltimore.

Drs. D. Emerick Szilagyi, Rajka R. Margulis and Roy D. McClure, Detroit, presented a paper on "Pituitary Adrenocorticotropic Hormone (ACTH) and Cortisone in the Management of Postoperative Complications and Related Problems." This paper was discussed by Drs. David M. Hume, Boston, and Geza DeTakats, Chicago.

Drs. Stanley R. Friesen and William N. Harsha, Kansas City, Kans., presented a paper on "Massive Generalized Wound Bleeding During Operation with Clinical and Experimental Evidence of Blood Transfusion Reactions." This paper was discussed by Drs. Jonathan E. Rhoads, Philadelphia, and J. Garrott Allen, Chicago.

THURSDAY, JUNE 14—AFTERNOON

The following officers were elected: chairman, Dr. I. Mims Gage, New Orleans; vice chairman, Dr. R. K. Gilchrist, Chicago; secretary, Dr. I. Ridgeway Trimble, Baltimore; representative on the American Board of Surgery, Dr. John Waugh, Rochester, Minn.; representative to the Scientific Exhibit, Dr. Walter G. Maddock, Chicago; delegate, Dr. Grover C. Penberthy, Detroit; alternate, Dr. Isaac A. Bigger, Richmond, Va.

Dr. I. S. Ravdin, Philadelphia, presented the chairman's address, entitled "The Responsibility of the Surgeon to Modern Society."

Drs. Waltman Walters, James T. Priestley and Hiram H. Belding III, Rochester, Minn., presented a paper on "Vagotomy in the Treatment of Gastrojejunal Ulceration: A Postoperative Clinical and Laboratory Study (A Study of 103 Cases)." This paper was discussed by Drs. I. Ridgeway Trimble, Baltimore; Lester R. Dragstedt, Chicago; Sara M. Jordan, Boston, and Hyman I. Goldstein, Camden, N. J.

Drs. Owen H. Wangensteen and Thomas O. Murphy, Minneapolis, presented a paper on "Gastric Resection with Restoration of Anatomic Continuity for Peptic Ulcer." This paper was discussed by Drs. Ralph Colp, New York; Lester R. Dragstedt, Chicago, and Richard B. Cattell, Boston.

Dr. Henry G. Hollenberg, Little Rock, Ark., read a paper on "Bleeding from the Nipple," which was discussed by Drs. William T. Fitts Jr., Philadelphia, and John V. Goode, Dallas, Texas.

Drs. Thomas J. E. O'Neill, Robert P. Glover and Charles P. Bailey, Philadelphia, presented a paper on "Observations on the Surgical Treatment of Mitral Stenosis by Commisurotomy." This paper was discussed by Drs. George D. Geckeler, Philadelphia, and Claude S. Beck, Cleveland.

FRIDAY, JUNE 15—AFTERNOON

Drs. Robert M. Zollinger and Mary M. Martin, Columbus, Ohio, presented a paper on "Surgical Aspects of Hypersplenism." This paper was discussed by Dr. Louis M. Rousselot, New York.

Drs. Arthur H. Blakemore, Stanley E. Bradley, Hugh F. Fitzpatrick, Cheves M. Smythe and Samuel R. Powers Jr., New York, presented a paper on "Physiological Studies on the Portal System in Cases of Portal Hypertension Requiring a Portacaval Anastomosis." This paper was discussed by Drs. Robert R. Linton, Brookline, Mass., and Ralph A. Deterling, New York.

Dr. Richard B. Cattell, Boston, read a paper on "Factors Influencing Prognosis in Carcinoma of the Colon and Rectum," which was discussed by Drs. Harry J. Warthen, Richmond, Va., and Samuel McLanahan Jr., Baltimore.

Dr. Frank J. McGowan, New York, read a paper on "More Frequent Use of Anterior Resection in the Sigmoid Colon for Cases of Recurrent or Chronic Diverticulitis." This paper was discussed by Drs. Frank Glenn and Louis M. Rousselot, New York.

Drs. Harry E. Bacon, Philadelphia, and Lloyd F. Sherman, Minneapolis, presented a paper on "The Surgical Management of Anomalies of the Anus, Rectum and Sigmoid Colon," which was discussed by Dr. Monte Edwards, Baltimore.

Drs. Morris L. Parker and Gerald J. Menaker, Chicago, presented a paper on "Evaluation of Indications for Exploration of the Common Duct." This paper was discussed by Drs. Leo M. Zimmerman, Chicago, and Richard B. Cattell, Boston.

SECTION ON UROLOGY

WEDNESDAY, JUNE 13—MORNING

The meeting was called to order at 9:05 a. m. by the chairman, Dr. John Arthur Taylor, New York.

Dr. Oswald S. Lowsley, New York, read a paper entitled "Further Experiences with the Fat-Ribbongut Method of Repairing Kidney Wounds."

A paper entitled "Rupture of the Urethra at the Apex of the Prostate," was presented by Drs. John K. Ormond and Philip W. Fairey, Detroit.

These two papers were discussed by Drs. Albert E. Goldstein, Baltimore; George A. Fiedler, New York; Harold P. McDonald, Atlanta, Ga.; E. J. McCague, Pittsburgh; Oswald S. Lowsley, New York, and John K. Ormond, Detroit.

Dr. Robert B. McIver, Jacksonville, Fla., read a paper entitled "Surgery of the Fused Kidney."

A paper entitled "Nephrostomy Drainage with Ureteral Splint in Renal Surgery," was presented by Drs. H. Haynes Baird and Hamilton W. McKay, Charlotte, N. C.

A paper entitled "Infection in Urinary Tract Calculi: Incidence and Management," was presented by Drs. James C. Kimbrough and William H. Morse, Washington, D. C.

These three papers were discussed by Drs. David M. Davis, Philadelphia; Oswald S. Lowsley, New York; Henry K. Sangree, Philadelphia, and Harold P. McDonald, Atlanta, Ga., and Drs. McIver, McKay and Kimbrough.

A paper entitled "The Clinical Effect of Estrogen Therapy on Metastatic Lesions from Carcinoma of the Testis," was presented by Drs. Charles H. de T. Shivers and Herbert B. Axilrod, Atlantic City, N. J.

Dr. William P. Herbst, Washington, D. C., read a paper entitled "Metabolic Management of Advanced Prostatic Malignancy."

These two papers were discussed by Drs. Edward N. Cook, Rochester, Minn., and William A. Milner, Albany, N. Y., and Drs. Shivers and Herbst.

THURSDAY, JUNE 14—MORNING

The following officers were elected: chairman, Dr. John R. Hand, Portland, Ore.; vice chairman, Dr. Rex Van Duzen, Dallas, Texas; secretary, Dr. Earl E. Ewert, Boston; delegate, Dr. Jay J. Crane, Los Angeles; alternate, Dr. Rex Van Duzen, Dallas, Texas; representative to Scientific Exhibit, Dr. Roger W. Barnes, Los Angeles.

A paper entitled "Treatment of Benign Prostatic Hypertrophy: Evaluation of the Transurethral, Perineal and Retropubic Methods," was presented by Drs. Kent A. Alcorn and Marshall W. Alcorn, Bay City, Mich.

Dr. Willard E. Goodwin, Baltimore, read a paper entitled "Surgical Problems Encountered in Radical Prostatectomies After Previous Operation on the Prostate."

Dr. Vernon S. Dick, Boston, read a paper entitled "Unrecognized Prostatism."

These three papers were discussed by Drs. Lowrain E. McCrea, Philadelphia; Samuel A. Vest, Charlottesville, Va.; Charles A. W. Uhle, Philadelphia; Roger W. Barnes, Los Angeles; Albert E. Goldstein, Baltimore; John K. Ormond, Detroit; John L. Emmett, Rochester, Minn.; Jay J. Crane, Los Angeles; Ralph Hathaway Jenkins, New Haven, Conn.; Marshall W. Alcorn, Bay City, Mich.; Willard E. Goodwin, Baltimore, and Vernon S. Dick, Boston.

A paper entitled "Atrophic Pyelonephritis vs. Congenital Hypoplasia," was presented by Drs. John L. Emmett, J. J. Alvarez and John R. McDonald, Rochester, Minn.

A paper entitled "A Classification of Uremia and Differential Diagnosis of the Causes of Uremia," was presented by Drs. Roger W. Barnes, Walter E. Macpherson, R. Theodore Bergman and Gordon Hadley, Los Angeles.

These two papers were discussed by Drs. William J. Engel, Cleveland; Edward H. Ray, Lexington, Ky.; Samuel E. Kramer, Perth Amboy, N. J.; John L. Emmett, Rochester, Minn., and Roger W. Barnes, Los Angeles.

Dr. Jay J. Crane, delegate, gave a short report on the activities of the House of Delegates.

Dr. C. D. Creevy, Minneapolis, read a paper entitled "Some Factors in Absorption After Ureterosigmoidostomy."

Dr. Walter M. Kearns, Milwaukee, read a paper entitled "Ureteral Intestinal Anastomosis."

These two papers were discussed by Drs. Clarence G. Bandler, New York; James C. Kimbrough, Washington, D. C.; C. D. Creevy, Minneapolis, and Walter M. Kearns, Milwaukee.

FRIDAY, JUNE 15—MORNING

A joint meeting was held with the Section on Anesthesiology. The proceedings are reported in the minutes of that section.

MEDICAL NEWS

CALIFORNIA

Society News.—New officers of the Los Angeles Obstetrical and Gynecological Society are Dr. Gordon Rosenblum, president, and Dr. Aaron N. Webb, secretary-treasurer.

State Medical Election.—The California Medical Association at its meeting May 13-16 installed Dr. H. Gordon MacLean, Oakland, as president and chose Dr. Lewis A. Alesen, Los Angeles, president-elect, and Dr. Donald A. Charnock, Los Angeles, speaker of the house of delegates.

ILLINOIS

University Appointment.—Dr. George G. Jackson, Boston, has been appointed assistant professor of preventive medicine at the University of Illinois College of Medicine. Dr. Jackson held joint appointments as Milton fellow in medicine at Harvard, research fellow at the Thorndike Memorial Laboratory, and assistant in medicine at Boston City Hospital.

Chicago

New Biochemistry Department.—The departments of chemistry and experimental medicine at Northwestern University Medical School are being combined into the department of biochemistry. Dr. Smith Freeman, who has been professor and chairman of the department of experimental medicine, has been named chairman of the newly established department.

Northwestern Names Abbott Professors.—Abbott Professors for the academic year 1951-52 at Northwestern University's Medical School are Dr. Carl A. Dragstedt, professor and chairman of the department of pharmacology; Henry B. Bull, Ph.D., professor in the department of chemistry; Fred S. Grodins, Ph.D., professor in the department of physiology, and Dr. E. Albert Zeller, associate professor in the department of chemistry. The four men will engage in medical research made possible by a $1,500,000 gift Northwestern received in 1939 from the estate of the late Clara A. Abbott, widow of Dr. Wallace C. Abbott.

Personals.—Dr. Jules H. Masserman, associate professor of nervous and mental diseases at Northwestern University and scientific director of the National Foundation for Psychiatric Research, has been appointed consultant to the secretariat of the United Nations and designated by the World Health Organization to present a series of lectures at universities throughout Europe and Scandinavia in October and November. Dr. Masserman will also address the British Royal Society.——Dr. Ole C. Nelson, medical director of Cook County Hospital, was guest of honor at a dinner June 13 marking the 41st year of his employment at the hospital. Dr. Nelson has been medical director since December 1943.

KANSAS

State Medical Election.—At the annual meeting of the Kansas Medical Society in Topeka, May 14-17, Dr. Clarence H. Benage, Pittsburg, was installed as president. Elected officers include Dr. Warren F. Bernstorf, Winfield, president-elect; Dr. John L. Lattimore, Topeka, treasurer, and Dr. John M. Porter, Concordia, delegate to the American Medical Association 1952-1954, with Dr. Peter E. Hiebert, Kansas City, as alternate.

MASSACHUSETTS

New Home Care Program.—Massachusetts General Hospital is to begin a new home care program to carry the services of the institution to needy families in the surrounding area. The plan, which is part of a 10-year program for improvement of basic care, teaching, and research, is expected to make better supervision of treatment possible and "make unnecessary many admissions to the hospital and permit patients to go home much earlier."

MICHIGAN

Dr. Deyton to Direct Multiple Sclerosis Center.—Dr. John W. Deyton, Detroit, has been appointed medical director of the Detroit Multiple Sclerosis Center, Detroit Memorial Hospital, succeeding Dr. Abe S. Goldstein, who has gone into private practice but will continue as consultant at the center. It is reported that thus far 370 of the state's estimated 4,000 sclerosis victims have been examined at the center.

Dr. Foster Made Emeritus Professor.—Dr. Linus J. Foster, who is retiring from active teaching this summer after 25 years at the Wayne University College of Medicine, Detroit, has been made *emeritus professor of clinical neurology and psychiatry.* Dr. Foster joined the college of medicine staff as an instructor in clinical neurology and psychiatry in 1926. He was promoted to assistant professor in 1931 and to professor in 1936.

MISSOURI

Dr. Proetz Receives Award.—Dr. Arthur W. Proetz, St. Louis, was recently awarded the De Roaldes gold medal of the American Laryngological Association. The award, made only six times previously since its establishment in 1907, is made "in special recognition of merit and achievement in teaching, authorship, and research." Dr. Proetz is professor of clinical otolaryngology at Washington University School of Medicine, is author of "Physiology of the Nose," and has written chapters and sections in numerous textbooks and monographs.

Gift of Roentgenograms for Teaching.—Dr. LeRoy Sante, professor of radiology at St. Louis University School of Medicine, has presented the school with some 1,500 miniature roentgenographs to be used in teaching the principles of roentgenologic interpretation. Selected x-rays from those compiled over 35 years of practice were reduced in size and filed in proper sequence, so that it is now possible to show students the original roentgenograms of a case and follow an illness to completion through the changes which occurred. Dr. Sante estimates it took most of his spare time over a period of two or three years to edit the series, sort it, and place the films in the order in which they should be used.

NEW YORK

Dr. Willard Named Dean at Syracuse.—Dr. William Robert Willard, formerly associate professor of public health and assistant dean in charge of postgraduate medical education at the Yale University School of Medicine has been appointed dean of New York State University College of Medicine at Syracuse. This position was vacated by the resignation of Dr. Herman G. Weiskotten, who has served the college as dean for 25 years. Dr. Willard was graduated cum laude from Yale with the M.D. degree in 1934 and the doctor of public health degree three years later. He interned at Johns Hopkins Hospital. Following a period as deputy state and county health officer in Maryland, he was surgeon in the U. S. Public Health Service. With the U. S. Army he was assigned to malaria control work.

Symposium on Pediatrics.—This symposium is being presented before the Suffolk County Medical Society on July 25 at 10 a. m. in the Central Islip State Hospital in Central Islip. Speakers include:

Horace L. Hodes, Manhasset, Common Forms of Meningitis.
Bernard Benjamin, Brooklyn, Changing Concepts in Fluid Therapy in Pediatrics.
Thomas V. Santulli, New York, Common Pediatric Abdominal Surgery.

The symposium is part of the postgraduate instruction arranged by the Medical Society of the State of New York in cooperation with the New York State Department of Health.

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

OHIO

Andrus Premedical Scholarship at Oberlin.—The establishment of a permanent premedical scholarship at Oberlin College in honor of the late Dr. William DeWitt Andrus, New York surgeon, was announced June 14. The scholarship, created by individual gifts from about 275 former patients, friends, and relatives of Dr. Andrus, will be awarded every two years to a second semester sophomore taking premedical work at Oberlin. Income from the scholarship endowment will assure, at the minimum, tuition for his junior and senior years. About 15% of the men in each sophomore class plan medical careers. Selection of the first Andrus Scholar will be made this spring by the Oberlin Men's Scholarship Committee with the assistance of premedical advisors. The scholar will be chosen on the basis of scholastic ability, aptitude for a career in medicine, character and citizenship, and financial need. Dr. Andrus took his premedical work at Oberlin College, and at the time of his death last Jan. 20 he was attending surgeon at the New York Hospital and professor of clinical surgery in Cornell University Medical College.

OKLAHOMA

Narcotic Violations.—Dr. Cosby Elwood Ford, Taft, on April 20 pleaded guilty to a violation of the federal narcotic law in the United States District Court at Muskogee. His sentence of 18 months was suspended, and he was placed on probation for three years and fined $300.

Dr. J. Walter Beyer, Tulsa, pleaded guilty to a violation of the federal narcotic law in the United States District Court at Tulsa, and on May 8 was sentenced to serve a term of two years.

PENNSYLVANIA

Heart Association Clinic.—The heart clinic, which was opened at the Pottsville Mission in Pottsville on June 14, will be open every Thursday morning to patients referred by their family physicians. It is being operated by Dr. Norman M. Wall and Dr. Joseph C. Koch, local physicians. The heart association will provide the services of specialists from metropolitan areas when such examination and treatment becomes necessary. Results of the examinations at the clinic will be referred to the family physician.

Philadelphia

Dr. Griffith Honored.—Ivor Griffith, Ph.D., who has just completed his 10th year as president of the Philadelphia College of Pharmacy and Science, was honored at the annual spring alumni reunion dinner of the college May 24. A tooled testimonial book and a doctor's cap and gown were among the presentations made to Dr. Griffith.

Laennec Society Prize.—The Laennec Society of Philadelphia will award a prize of $200 for the best paper submitted in any field related to diseases of the chest. This prize is open to undergraduates, interns, residents, or fellows throughout the United States. The work should be original and not a review of the literature or previous contributions. The society requests that the prize-winning paper be presented at one of its regular scientific meetings. Five copies of the manuscript should be submitted, double-spaced with wide margins, to Dr. Katharine R. Boucot, 311 S. Juniper St., Philadelphia 7, by Oct. 1.

New Aero-Medical Laboratory.—Dr. Robert F. Rushmer, of the University of Washington, Seattle, has been appointed superintendent of the scientific department of the Aviation Medical Acceleration Laboratory of the U. S. Navy, located at Johnsville, Pa. The appointment was made in accordance with an agreement signed by Harold E. Stassen, president of the University of Pennsylvania, and Captain Selden B. Spangler, whereby the university and the U. S. Naval Air Development Center have become affiliated. Personnel of the two institutions and the faculty of the university school of medicine will cooperate with the commander of NADC in the selection of personnel for the laboratory of the center. Dr. Rushmer has also been appointed professor of applied physiology on the faculty of the university's school of medicine; other appointees at the laboratory will receive appropriate faculty appointments in the university. One of the main functions of the new laboratory will be the study of man's reactions to acceleration under conditions resembling stress patterns encountered in air combat. It has been designed as a complete aero-medical laboratory well equipped for work in physiology, animal surgery, radioactivity, biophysics, biochemistry, gas analysis, pathology and electronics, and it also has a medical library, conference rooms, and service and fabrication shops. From 1940 to 1942 Dr. Rushmer was a fellow at the Mayo Clinic, Rochester, Minn., and in 1941 was appointed an assistant in aviation medicine. He served as a research projects officer, department of clinical investigation, with the School of Aviation at Randolph Field, Texas, from 1942 to 1946 inclusive. After the war Dr. Rushmer joined the medical faculty at the University of Southern California School of Medicine, Los Angeles, as an associate professor of aviation medicine and in 1947 went to the University of Washington to serve in the same field of activities.

SOUTH DAKOTA

State Medical Election.—At the annual meeting of the South Dakota State Medical Association in Aberdeen, June 2-6, Dr. David A. Gregory, Milbank, was installed as president. Elected officers include Dr. Roy E. Jernstrom, Rapid City, president-elect; Dr. Roland G. Mayer, Aberdeen, vice president; Dr. Louis J. Pankow, Sioux Falls, secretary-treasurer, and Dr. Alonzo P. Peeke, Volga, speaker of the house. The association's first annual award to the outstanding doctor in South Dakota was given to Dr. Theodore F. Riggs of Pierre.

TENNESSEE

Women Aid Children's Hospital.—A group of women from four counties in middle Tennessee, members of the Hospital Children's Aid League, are serving the Emerald-Hodgson Hospital in Sewanee, where last year 68% of the services extended to children were free. The Children's Aid League was formed in response to the need for furnishings for the linen closet for the children's wing then under construction. In a drive designed to raise $1,000, these women raised $4,500. This year's project was the Surprise Shop, at Winchester, where contributions ranging from frying pans to chandeliers were collected from here and there and sold to aid the Children's Fund. Officers of the League are Mrs. Kirby-Smith, Sewanee, chairman; Mrs. Blevins Rittenberry, Cowan, secretary, and Mrs. Bob Winton, Decherd, treasurer. The Emerald-Hodgson Hospital is located on property of the University of the South and is owned and operated by the university and the Episcopal Church.

TEXAS

State Medical Election.—At the annual meeting of the State Medical Association of Texas in Galveston, April 29-May 2, Dr. William M. Gambrell, Austin, was installed as president. Elected officers include Dr. Truman C. Terrell, Fort Worth, president-elect; Dr. Samuel N. Key, Austin, secretary, and Dr. Robert B. Homan Jr., El Paso, speaker of the house of delegates.

WEST VIRGINIA

Psychiatric Bulletin.—A new quarterly publication is being sponsored by the bureau of mental health of the state department of health. The publication, known as *The Psychiatric Bulletin,* will be circulated throughout the state to doctors, libraries, hospitals, industrial plants, and county and district health departments. The initial issue will be distributed in July.

WISCONSIN

Training for School Physicians.—During the week of June 11-15, Dr. Mary P. Warner, pediatric consultant of the Washington County Health Department, Maryland, held an in-staff training seminar for school physicians in Milwaukee at the invitation of the Milwaukee Health Department. Other participants in the seminar were Dr. Max E. Wiese, Milwaukee, Dr. Margaret E. Hatfield, Milwaukee, and Dr. Virginia S. Downes, Jackson, Miss. Discussions of school health programs lead by Dr. Warner were also held with the nursing staff and dental staff of the Milwaukee Health Department and with members of the Milwaukee School Board.

GENERAL

Society Election.—At its recent meeting the American Ophthalmological Society elected the following officers for 1951-52: Dr. Lawrence T. Post, St. Louis, president; Dr. Conrad Berens, New York, vice president; Dr. Maynard C. Wheeler, New York, secretary-treasurer, and Dr. Gordon M. Bruce, New York, editor.

Dr. Alvarez Awarded Medal.—Dr. Walter C. Alvarez, Chicago, recently was awarded the 1951 Friedenwald Medal, an award given annually to one of the senior members of the American Gastroenterological Association for outstanding work and distinguished service in the field of gastroenterology. The medal was presented to Dr. Alvarez at the annual scientific session of the association which was held in June in Atlantic City.

Dermatological Association Prizes.—In the annual essay contest sponsored by the American Dermatological Association to stimulate younger investigators to original work, Dr. Thomas B. Fitzpatrick, Rochester, Minn., won first place with his thesis, "The Tyrosinase Reaction as a Specific Index of Malignance of Pigment Cell Neoplasms, with Particular Reference to Malignant Melanoma." He presented his essay at the association meeting in Hot Springs, Va., in May and received a cash award of $300. Honorable mention was awarded to Dr. S. William Becker Jr., Rochester, Minn., for his paper on "The Dendritic Cell of the Epidermis" and to Dr. Joseph W. Goldzieher, New York, for his paper on "'Chemical' Analysis of the Intact Skin by Reflectance Spectrophotometry."

Outbreaks of Diphtheria.—The Maine Department of Health and Welfare reports an outbreak of 10 diphtheria cases in a state hospital. The first case was that of an attendant. Since May 6, two other attendants and seven patients have had diphtheria, with the outcome of one case (a patient aged 65) being fatal. Dr. Wilton L. Halverson, California State Department of Public Health, supplements a previous report of diphtheria in one of the northern counties. During May, 10 cases were reported. Two of the patients were nurses aides (aged 21 and 48 years) who had had contact with two diphtheria patients before the diagnosis of diphtheria was established. One patient was a hospital janitor (aged 69 years), and two others were ward patients (aged 82 and 86 years) in this hospital.

Dr. Edwin Jordan Appointed Executive Director.—The American Association of Medical Clinics has appointed Dr. Edwin P. Jordan as its executive director. Dr. Jordan was for several years previous to 1947 an associate editor of The Journal. From 1947 to 1950 he was director of education of the Frank E. Bunts Educational Institute and the Cleveland Clinic Foundation. Among his new duties will be the development of a program of graduate medical education in private medical clinics equipped for such activity. The American Association of Medical Clinics was formed in 1949 and recently had 62 member clinics representing about 1,500 physicians. Officers elected at the December meeting are Drs. Wallace M. Yater, Washington, D. C., president; Clair L. Stealy, San Diego, Calif., vice president, and Arthur H. Griep, Evansville, Ind., secretary-treasurer.

Death Rates Decline in Many Countries.—Extensive application of the recent advances in medicine has improved health conditions throughout the world, Metropolitan Life Insurance Company statisticians report. A comparison of death rates just before and after World War II shows that in each of 19 countries in both hemispheres the rate has declined by more than 8%, and in nine of these countries it has dropped 20% or more. In Japan the death rate fell by 30%, largely as the result of public health measures instituted by the American army of occupation. In Ceylon an anti-malaria campaign was an important factor in lowering the death rate during the postwar years, and in India the death rate has declined by about one fifth between the prewar and postwar years. Declines were also registered in Puerto Rico, Mexico, Costa Rica, Chile, and Venezuela. England and Wales experienced a mortality decline of 27%, and the United States a decline of 23%. Recent declines in mortality in the Western nations are credited in large measure to control of infectious diseases by means of chemotherapy and antibiotics.

Considers Health Program for Europe.—Guiding principles for international health programs directed in Europe by the World Health Organization were outlined by WHO's consultative committee for Europe at its first session in Geneva May 28-29. WHO's program on the continent is based on the principle that, in general, Europe is a developed area where health demonstration services are not so important as some other types of aid. For this reason the committee recommended that WHO stimulate health activities, coordinate health policies regarding problems shared by European countries, and exchange information and experience. Specific programs were recommended in the fields of housing, noninfectious chronic diseases of the adult population, dental hygiene, nutrition, regular health examination of the population, rehabilitation of tuberculous patients, and regional technical discussions. The committee recommended continuation of group projects as well as individual fellowships, especially in public health administration, mental hygiene, and other fields of major importance in Europe. Another session of the committee will be held at Geneva in the autumn to draft concrete proposals for the 1953 program.

Diabetes Victims Warned of Dangerous Remedy.—The known diabetics of the United States were warned July 5 that a diabetic remedy that is being mailed from Mexico is worthless and extremely dangerous if employed as a substitute for insulin. The U. S. Food and Drug Administration, with the cooperation of customs and postal authorities, has been able to prevent delivery of about 20 individual packages of the nostrum, which is advertised and labeled as "Cacalia Composita, Mexican Indian Root." It is being offered by the "Mexican Indian Root Co., Mexico City." Circulars give the name of "Dr. Miguel C. Martinez, general manager."

Advertisements for the remedy have been appearing in newspapers and magazines throughout the country. Cities where the advertisements are known to have been published are San Francisco, Sacramento, Cal., New York, Cincinnati, Detroit, Pittsburgh, Philadelphia, Uniontown, Pa., and Bridgeport, Conn. Direct mail advertising is also being used to promote the remedy. FDA officials said the mailings were heavy in the Vermont area, but the packages which were denied entry were addressed to all sections of the country. The remedy has been priced at $15 and $25, cash in advance.

Atlantic City Golf Awards.—Dr. Frank H. Lahey, Boston, assumed the presidency of the American Medical Golfing Association at the close of the recent Seaview Tournament in Atlantic City, N. J. Dr. Thomas A. Kyner, Kansas City, Mo., was chosen as the president-elect, Dr. Eugene P. Pendergrass, Philadelphia, first vice president, and Robert W. Elwell, Delanco, N. J., secretary-treasurer. The 36th annual meeting of the AMGA will be held in Chicago next June on the first Monday of the 1952 AMA annual meeting.

Dr. Vincent W. Guidice, Ridgewood, N. J., won the low gross championship for 18 holes and was presented the Golden State trophy. Dr. Harold T. Sargis, Cleveland, took the 36 hole gross title, winning the Will Walter trophy. Other trophy awards to the 264 medical golfers participating went to Dr. Gerald F. Dederick Jr., Oradell, N. J., the Detroit trophy as runner up for the 36 hole championship; Dr. Lewis R. Wolf, Philadelphia, the Ben Thomas trophy as the runner up in the 18 hole event; Dr. Edward J. Kempf, Wading River, N. Y., the St. Louis trophy for the best net 36 holes; and Dr. Gilbert M. Bayne, Glen Olden, Pa., the President's trophy for the best net score for the first flight of 18 holes. For the fifth time Dr. David H. Houston, Seattle, was the winner of the Wendell Phillips trophy for the best low net 18 holes among the past presidents of the AMGA.

CORRECTION

Course in Exfoliative Cytology (Cancer Detection).—The Office of the Dean of Cornell University Medical College, New York, points out that the postgraduate course, third from the top on page 584 of The Journal, June 9, 1951, should have been listed under "Malignant Disease" rather than under "Dermatology and Syphilology." This course will be repeated again beginning March 3, 1952.

Regulations for Diathermy Equipment.—In the item "Regulations for Diathermy Equipment" in The Journal June 2, 1951 (page 481), the channel frequency assignments were given as 13.66, 27.33, and 40.98 megacycles. These frequencies have been changed by the Federal Communications Commission to 13,560 kilocycles plus or minus 6.78 kilocycles; 27,120 kilocycles plus or minus 160 kilocycles, and 40,680 kilocycles plus or minus 20 kilocycles. From a therapeutic standpoint, these changes are of no consequence.

EXAMINATIONS AND LICENSURE

NATIONAL BOARD OF MEDICAL EXAMINERS

National Board of Medical Examiners: *Parts I and II.* Various Centers. Sept. 5-7 (Part I only). Applications must be filed at least thirty days prior to an examination. Ex. Sec., Mr. E. S. Elwood, 225 S. 15th Street, Philadelphia.

INTERNATIONAL COLLEGE OF SURGEONS

Examinations for Certified Fellowship in the United States Chapter in General and Orthopedic Surgery, Chicago, Aug. 3-4. Sec., Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago 10.

EXAMINING BOARDS IN SPECIALTIES

American Board of Anesthesiology: *Written.* July 20. Given simultaneously in several cities in the United States. Final date for filing application was Jan. 20. *Oral.* Memphis, Oct. 14-17. *Written.* July 18, 1952, Various locations. Final date for filing applications is Jan. 18, 1952. Sec., Dr. Curtiss B. Hickcox, 80 Seymour St., Hartford 15, Conn.

American Board of Internal Medicine: *Written.* Various centers, Oct. 15. Final date for filing applications was May 1. *Oral.* The schedule of oral examinations for 1951 has been arranged on a regional basis as follows: New York, date to be announced, covering Maine, Massachusetts, New Hampshire, New York and Vermont. San Francisco, date to be announced, covering Arizona, California, Colorado, Idaho, Montana, New Mexico, Oregon, Utah and Washington.
Only candidates who have not taken an oral examination can be admitted under the schedule arranged thus far.
Closing dates for the filing of applications for examinations in New York and San Francisco to be announced.
Oral examinations in the subspecialties will be held at the same time and place and on the same distribution.
Exec. Sec., Dr. William A. Werrell, 1 West Main Street, Madison 3.

American Board of Neurological Surgery: *Oral.* Chicago, Oct. 25-26. *Oral* Chicago, May 1952. Final date for filing applications for the May 1952 examination is Jan. 1, 1952. Sec., Dr. W. J. German, 789 Howard Ave., New Haven 4, Conn.

American Board of Obstetrics and Gynecology: *Written.* Feb. 1, 1952. Final date for filing applications is Nov. 1. *Oral.* Chicago, June 7-13, 1952. Final date for filing application is Feb. 1, 1952. Sec., Dr. Paul Titus, 1015 Highland Building, Pittsburgh 6, Pa.

American Board of Ophthalmology: *Written.* Twenty-five centers, Feb. 4-5, 1952. *Oral.* Chicago, October 8-13. Sec., Dr. Edwin B. Dunphy, 56 Ivie Road, Cape Cottage, Maine.

American Board of Orthopaedic Surgery: Final date for filing applications for the 1952 Part II examinations is Aug. 15, 1951. Sec., Dr. Harold A. Sofield, 122 S. Michigan Ave., Chicago 3.

American Board of Otolaryngology: *Oral.* Chicago, Oct. 8-12. Sec., Dr. Dean M. Lierle, University Hospital, Iowa City.

American Board of Pediatrics: *Oral.* Buffalo, Oct. 26-28. Ex. Sec., Dr. John McK. Mitchell, 6 Cushman Road, Rosemont, Pa.

American Board of Preventive Medicine: *Written.* San Francisco, October 28. *Oral.* San Francisco, October 29. Sec., Dr. Ernest L. Stebbins, 615 North Wolfe St., Baltimore 5.

American Board of Proctology: Philadelphia, Nov. 17-18. Sec.-Gen., Dr. Louis A. Buie, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Radiology: *Oral.* Washington, D. C., Sept. 17-22. Sec., Dr. B. R. Kirklin, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Surgery: *Written.* Various centers, Oct. 1951. Final date for filing applications is July 1. Sec., Dr. J. Stewart Rodman, 225 South 15th Street, Philadelphia.

Board of Throacic Surgery: *Written.* Various parts of the country. Sept. 14, 1951. Final date for filing applications is July 15. Sec., Dr. William M. Tuttle, 1151 Taylor Ave., Detroit 2, Mich.

American Board of Urology: Chicago, Feb. 9-13, 1952. Final date for filing applications is Sept. 1. Sec., Dr. Harry Culver, 314 Corn Exchange Bldg., Minneapolis 15.

MEETINGS

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 6-8. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American Congress of Physical Medicine, Shirley-Savoy Hotel, Denver, Sept. 4-8. Dr. Walter J. Zeiter, 2020 E. 93d St., Cleveland 6, Executive Director.

National Medical Association, Philadelphia, Aug. 20-24. Dr. John T. Givens, 1108 Church Street, Norfolk 10, Va., General Secretary.

Post Graduate Medical Assembly of South Texas, Shamrock Hotel, Houston, Texas, July 23-25. Mrs. W. H. Dahme, 229 Medical Arts Bldg., Houston, Executive Secretary.

Reno Surgical Society Conference, Riverside Hotel, Reno, Nev., Aug. 23-25. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nev., Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 9-11. Dr. Maurice D. Frazer, 1037 Stuart Building, Lincoln, Nebr., Secretary.

West Virginia State Medical Association, The Greenbrier, White Sulphur Springs, July 19-21. Mr. Charles Lively, 1031 Quarrier St., Charleston 24, Executive Secretary.

INTERNATIONAL

Association Internationale de Psychotechnique, Gothenburg, Sweden, July 24-28. Dr. Franziska Baumgarten-Tramer, Thunstrasse 35, Berne, Switzerland.

European Congress on Rheumatism, Barcelona, Spain, Sept. 24-27. Dr. Gunnar Edströn, Sweden, Secretary.

General Practitioners Study Club International, Rome, Italy, Sept. 12-15. Dr. John O'Connell, 10300 Lackland Road, St. Louis 14, Mo., U. S. A., President.

International Anesthesia Research Society, London, England, Sept. 3-7. Mr. R. W. Cope, University College Hospital, London W.C.1, England.

International Association of Allergists, Zurich, Switzerland, Sept. 23-29. Prof. A. S. Grumbach, Hygiene Institut der Universitaet Zurich, Gloriastr. 32, Zurich, Switzerland.

International Congress of Anesthesiology, Nursing School of the Salpiettre, 47 Boul de l'Hospital, Paris, France, Sept 20-22. 12 rue de Seine, Paris 6ᵉ, France, Secretariat.

International Congress of Clinical Pathology, London, England, July 16-20. Dr. W. H. McMenemey, Maida Vale Hospital for Nervous Diseases, London W.9, England, Secretary.

International Congress on Industrial Medicine, Instituto Superior Técnico, Lisbon, Portugal, Sept. 9-15. Dr. Luis Guerreiro, Instituto Nacional do Trabalho e Previdência, Praça do Comercio, Lisbon, Secretary General.

International Congress on Mental Health, Mexico City, Mexico, Dec. 11-19. Mrs. Grace E. O'Neill, Division of World Affairs, National Association on Mental Health, 1790 Broadway, New York 19, N. Y.

International Congress of Physical Medicine, London, England, July 14-19. Dr. A. C. Boyle, 45, Lincoln's Inn Fields, London, W.C.2, England, Honorary Secretary.

International Congress of Psychology, Stockholm, Sweden, July 16-21. Secretariat: Psychological Institute, Observotoriegatan 8, Stockholm, Sweden.

International Gerontological Congress, Hotel Jefferson, St. Louis, Mo., U. S. A., Sept. 9-14. Dr. John E. Kirk, 5600 Arsenal Street, St. Louis 9, Mo., Chairman, Program Committee.

International Hospital Congress, Brussels, Belgium, July 15-21. Capt. J. E. Stone, 10 Old Jewry, London E.C., England, Secretary.

International Poliomyelitis Congress, Copenhagen, Denmark, Sept. 3-7. Prof. Dr. Niels Bohr, Statens Seruminstitut, 80 Amager Blvd., Copenhagen S., Denmark, President.

International Society of Surgery, Paris, France, Sept. 24-29. Dr. L. Dejardin, 141, rue Belliard, Brussels, Belgium, Secretary General.

International Society for the Welfare of Cripples, Fifth World Congress, Stockholm, Sweden, Sept. 9-14. Mr. Donald V. Wilson, 54 E. 64th St., New York 21, N. Y., U. S. A., Executive Director.

Pan American Congress on Tuberculosis, Guayaquil and Quito, Ecuador, S. A., July 14-22. Dr. Marco Martinez M., Casilla de Correos No. 116, Guayaquil, Ecuador, Secretary General.

Pan Pacific Surgical Association Congress, Honolulu, Hawaii, Nov. 7-19. Dr. Forrest J. Pinkerton, Suite 7, Young Bldg., Honolulu, Hawaii, President.

Students' International Clinical Congress, Leyden, Utrecht, Groningen and Amsterdam, Holland, July 10-28. N. A. M. Bergstein, Oude Gracht 143 bis, Utrecht, Holland, Secretary General.

World Confederation for Physical Therapy, Copenhagen, Denmark, Sept. 7-8.

World Medical Association, Stockholm, Sweden, Sept. 15-21. Dr. Louis H. Bauer, 2 E. 103d St., New York 29, N. Y., U. S. A., Secretary-General.

DEATHS

Hektoen, Ludvig ⊕ internationally known pathologist and 1942 recipient of the Distinguished Service Medal of the American Medical Association, died at Michael Reese Hospital, Chicago, July 5, aged 88, of diabetes. Dr. Hektoen was born in Westby, Wis., July 2, 1863. He studied at Luther College, Decorah, Iowa, and at the University of Wisconsin. His medical career began with a job as druggist in a hospital, which became for him an inspiration to the study of medicine. He graduated in 1887 from the College of Physicians and Surgeons in Chicago, then served as apothecary in the Illinois Eastern Hospital for the Insane and subsequently made first place in the examination for internship at the Cook County Hospital. Here he came under the direct instruction of Christian Fenger. Dr. Hektoen served at Cook County Hospital from 1889 to 1903, as lecturer in pathology at Rush Medical College, 1890-1892, and for a period in the interim as curator of the museum, physician to the coroner's office in Chicago, 1890-1894, and as professor of pathology at the College of Physicians and Surgeons, 1892-1894. Returning to Rush Medical College as professor of morbid anatomy in 1895, he became professor of pathology in 1898, holding this title until 1933, when he became professor emeritus. He was professor and head of the department of pathology at the University of Chicago from 1901 to 1932.

Ludvig Hektoen, M.D.
1863-1951

Throughout his long career Dr. Hektoen was a member of innumerable scientific societies in this country and abroad, having spent several of his early years in postgraduate study in Upsala, Prague, and Berlin. He served as president of the Chicago Medical Society, 1919-1921; the Chicago Pathological Society, 1898-1902; the Association of American Pathologists and Bacteriologists, 1901; Society of American Bacteriologists, 1929, and the Society of Immunologists in 1927. Dr. Hektoen was a founder of the Institute of Medicine of Chicago (1915) and had been from the first active on its board of governors, serving as chairman from 1921 to 1940, when he was chosen honorary chairman. He was president of the institute in 1929. He was vice president of the American Association for the Advancement of Science in 1909 and of the Chicago Academy of Criminology in 1931. He served as chairman of the Division of Medical Sciences of the National Research Council for a year beginning in 1924, again for a year in 1926 and again in 1929. From 1936 to 1938 he was chairman of the National Research Council and from 1934 to 1938 a member of the National Advisory Health Council of the U. S. Public Health Service. At one time he was also a member of the board of trustees of Science Service, representing the National Research Council, and a member of the board of trustees of the American Documentation Institute.

Dr. Hektoen served the American Medical Association as chairman of the Provisional Section on Pathology, 1899-1900, chairman of the Section on Pathology and Bacteriology, 1900-1901, was a member of the House of Delegates in 1918 and 1920, and for many years was chairman of the Committee on Scientific Research, in which position he was instrumental in determining the distribution of grants for research.

Throughout much of his life Dr. Hektoen was engaged in the field of cancer, serving for many years as a member of the board of directors of the American Society for the Control of Cancer and from 1937 to 1944 as executive director of the National Advisory Cancer Council of the U. S. Public Health Service. In 1930 Dr. Hektoen was chosen chairman of the Cancer Research Institute of Chicago, which had been incorporated by the Chicago Woman's Club in 1929, and in 1941 he was named to a similar position for the Chicago Cancer Committee, which was organized as a liaison educational agency. He was one of the founders of the Chicago Tumor Institute and was president of its board of trustees until May, 1951, when he became president emeritus.

His literary contributions have shown an interest in many phases of medical science and his writings have been voluminous. He was editor of *The Journal of Infectious Diseases* from 1904, when it was first established, until 1941. The *Archives of Pathology*, of which he had been editor since its first appearance in 1926, dedicated its July 1938 issue to Dr. Hektoen in commemoration of his 75th birthday. He was at various times editor of the *Proceedings of the Institute of Medicine of Chicago* and of the *Transactions of the Chicago Pathological Society*. His published works include "The Technique of Post-Mortem Examination" and "Introduction to Study of Infectious Diseases." Notable scientific contributions first described by Dr. Hektoen include the term Hektoen's phenomenon: "When antigens are introduced into the animal body in allergic states, there may exist an increased range of new antibody production which may include production of antibodies concerned in previous infections and immunizations."

Dr. Hektoen had given many outstanding lectures, including the Pasteur, the Cutter, and the Fenger lectures. In recognition of his brilliant career as scientist, he was awarded in 1942 the Distinguished Service Medal of the American Medical Association. The previous year he had been accorded the centennial award of the Wisconsin State Medical Society for distinguished service and in 1929 the Order of St. Olaf from the Norwegian government. On July 2, 1943, the John McCormick Institute for Infectious Diseases, of which he had been a founder and director from 1902 to 1940, was rededicated in his honor as the Ludvig Hektoen Institute for Medical Research of Cook County. The occasion marked the 80th birthday of Dr. Hektoen and commemorated his many notable achievements in the fields of pathology, bacteriology, and immunology. Dr. Hektoen's ability as a student and scientist was further recognized in honorary degrees from Rush Medical College, the University of Norway, the University of Michigan, University of Wisconsin, University of Cincinnati, Western Reserve University, and the University of Chicago. In his death, the profession of medicine has lost a truly great physician, and our country, a truly great citizen.

⊕ Indicates Fellow of the American Medical Association.

Titus, Paul ⊕ for many years secretary-treasurer and director of the American Board of Obstetrics and Gynecology, died suddenly at his home in Pittsburgh June 28, aged 66, of coronary thrombosis. Dr. Titus was born in Batavia, N. Y., May 6, 1885. Following graduation from Yale University School of Medicine in New Haven, Conn., in 1908, he went to Heidelberg, Germany, where he became an assistant at the Universitäts Frauenklink, serving until 1910. Returning to this country, he served as an assistant in obstetrics at Johns Hopkins Hospital in Baltimore from 1910 to 1911, then became a resident obstetrician and gynecologist at the Elizabeth Steel Magee Hospital. He was affiliated at various times with the St. Margaret Memorial Hospital, Pittsburgh Hospital, Western Pennsylvania Hospital, and Shadyside Hospital in Pittsburgh and the Homestead Hospital in Homestead, Pa. He was secretary-treasurer of the Advisory Board for Medical Specialists from its inception in 1933 until 1941, vice president from 1943 to 1945, and president from 1945 to 1947. In 1933-1934 Dr. Titus served as vice chairman of the Section on Obstetrics, Gynecology and Abdominal Surgery of the American Medical Association. Through his activities on the Post Graduate Survey Committee of the American Board of Obstetrics and Gynecology, he worked with the Council on Medical Education and Hospitals of the American Medical Association on approval of residency programs. He was president of the Association of Yale Alumni in Medicine in 1942-1943, and of the Pittsburgh Academy of Medicine in 1929-1930. Long active in the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, Dr. Titus had been a member of its executive council from 1929 to 1935 and from 1939 to 1945, and served as president in 1937-1938. He was a member of the American Gynecological Society, serving as vice president in 1948-1949, and the Society Royale, Belge de Gynecologie et d'Obstétrique, and a fellow of the American College of Surgeons. In 1937 he was decorated by the Hungarian government with the Commander Cross of the Hungarian Order of Merit in recognition of his work in obstetrics. From 1915 to 1919 he was a civilian aide to the Military Special Agent for Naval Intelligence and in 1943-1944 was a consultant to the surgeon general of the United States Army. He entered the service July 22, 1944 as a lieutenant commander and later was promoted to Captain in the Naval Reserve and assigned to the Professional Division of the Bureau of Medicine and Surgery in Washington, D. C., until 1946. He was awarded the Navy Commendation Ribbon in 1945 and commended by Secretary of the Navy James Forrestal "for distinctive service in establishing a professional standard for intern and residency training in naval hospitals," and "for his cooperative efforts toward the establishment and professional classification of reserve medical officers and the procurement of important data." Since 1946 he had been a reserve consultant to the advisory board of the Bureau of Medicine of the Navy Department, and since 1948 a member of the Armed Forces Medical Advisory Committee. Dr. Titus was directing editor of the "Directory of Medical Specialists" from 1937 to 1947, and at the time of his death he was a member of the advisory editorial board of the *American Journal of Obstetrics and Gynecology*. He was the author of "Management of Obstetric Difficulties," 1937, second edition in 1940, third edition in 1945; "Diseases of Women for the General Practitioner," 1937, and "Atlas of Obstetric Technic," 1943, second edition in 1949.

Price, George Elmer ⊕ Seattle; born in Bridgeport, Pa., Feb. 10, 1874; University of Pennsylvania Department of Medicine, Philadelphia, 1898; specialist certified by the American Board of Psychiatry and Neurology; member of the American Medical Association, American Neurological Association, and the North Pacific Society of Internal Medicine; at one time practiced in Philadelphia, where he had been on the faculty of Jefferson Medical College and affiliated with Philadelphia General and Jefferson Medical College hospitals; consultant in neuropsychiatry at the U. S. Marine Hospital; served during World War I; died in Seattle General Hospital April 24, aged 77, of bronchopneumonia and carcinoma of the stomach.

Miller, Raymond Eugene, Clarkston, Mich.; Detroit Homeopathic College, 1904; died Feb. 1, aged 71, of coronary thrombosis and chronic nephritis.

Nelken, Bernard Earl ⊕ Baton Rouge, La.; Tulane University of Louisiana School of Medicine, New Orleans, 1924; specialist certified by the American Board of Internal Medicine; served during World War II; secretary of the East Baton Rouge Parish Medical Society; affiliated with Baton Rouge General Hospital and Our Lady of the Lake Sanitarium; died Feb. 9, aged 53, of coronary thrombosis.

Riley, Josephine, Chillicothe, Ohio; National University Medical Department, Washington, D. C., 1901; died in Chillicothe Hospital April 11, aged 88, of fracture of the left hip and arteriosclerosis.

Roberson, Arthur William, Chicago; Meharry Medical College, Nashville, Tenn., 1919; died April 25, aged 56, of concussion of the brain resulting from a fall.

Robinson, William Arthur, Ocean Grove, N. J.; Jefferson Medical College of Philadelphia, 1905; member of the American Medical Association; on the staff of the Monmouth Memorial Hospital in Long Branch and Fitkin Memorial Hospital in Neptune, where he died April 26, aged 69, of carcinoma of the pancreas.

Ryley, Harold William, East Rutherford, N. J.; Harvard Medical School, Boston, 1922; school physician; member of the American Medical Association; on the staff of the Hackensack (N. J.) Hospital, where he died April 19, aged 57.

Sanger, Fenton Mercer ⊕ Oklahoma City, Okla.; Epworth College of Medicine, Oklahoma City, 1907; member of the American Medical Association; served during World War I; died in April, aged 83, of coronary occlusion and arteriosclerosis.

Schnitter, Charles Henry, Grand Island, N. Y.; University of Buffalo School of Medicine, 1934; member of the American Medical Association; school physician; served on the staff of the Millard Fillmore Hospital in Buffalo; died April 25, aged 42, of congestive heart failure.

Seaman, James Alpheus ⊕ Springfield, Mass.; Columbia University College of Physicians and Surgeons, New York, 1919; specialist certified by the American Board of Urology; member of the American Urological Association; fellow of the American College of Surgeons; for many years secretary of the Springfield Academy of Medicine; on the staff of the Westfield (Mass.) State Sanatorium, Springfield Hospital, Holyoke (Mass.) Hospital, and Shriners Hospital for Crippled Children; died in Springfield Hospital April 21, aged 61, of cerebral hemorrhage.

Thompson, William C. ⊕ Westerly, R. I.; New York Homeopathic Medical College and Hospital, New York, 1903; member of the staff of Westerly Hospital; consultant on the staff of South County Hospital in Wakefield; died March 18, aged 74, of aortic stenosis and pulmonary infarct.

Thomson, Alexander ⊕ Detroit; Detroit College of Medicine, 1894; died April 2, aged 82, of acute coronary thrombosis.

Utter, John Charles, Mount Carmel, Ill.; Miami Medical College, Cincinnati, 1880; died April 15, aged 91, of injuries received in a fall.

Van Doren, William ⊕ Mechanicville, N. Y.; Albany (N. Y.) Medical College, 1889; an Associate Fellow of the American Medical Association; past president of the school board; died April 21, aged 85.

Van Vranken, Albert Bensen ⊕ Skaneateles, N. Y.; Columbia University College of Physicians and Surgeons, New York, 1900; formerly practiced in Schenectady, where he was on the staff of Ellis Hospital; died April 29, aged 77, of carcinoma.

Wallace, Harry Clay, Mount Healthy, Ohio; Medical College of Ohio, Cincinnati, 1900; died in Cincinnati April 17, aged 81, of cardiorenal disease.

Wilkin, W. Ernest ⊕ South Whitley, Ind.; Barnes Medical College, St. Louis, 1904; served on the staff of Lutheran Hospital in Fort Wayne; died April 16, aged 70, of cerebral hemorrhage.

Williams, Rodney Ralph ⊕ Dobbs Ferry, N. Y.; Cornell University Medical College, New York, 1908; member of the American Psychiatric Association; affiliated with the Children's Village; at one time on the staffs of the Binghamton (N. Y.) State Hospital and the Hudson River State Hospital in Poughkeepsie; served as consulting psychiatrist to the Westchester County Children's Court; died April 14, aged 68, of heart disease.

GOVERNMENT SERVICES

ARMY

Civilian Medical Care for Army Personnel.—The following statement, slightly abbreviated here, was submitted by the Surgeon General's office:

Adequate and timely medical care and treatment, including hospitalization, is provided for Army personnel in the United States generally by dispensaries, infirmaries, and hospitals located at the many Army installations throughout the country. However, there are many locations where Army or other United States federal medical treatment facilities are not available when medical service is required by Army personnel. In cases of this nature the services of civilian physicians, clinics, and hospitals are necessary. Certain criteria, in accord with current laws and regulations, define the conditions under which individuals of the Army may be authorized civilian medical care (other than elective) at the expense of the Army. Such care is authorized for commissioned officers, contract surgeons when employed by the Army on a full-time basis, warrant officers, enlisted personnel, cadets of the United States Military Academy, general prisoners, and prisoners of war, when these personnel are on a duty status or when they are absent from their place of duty, on leave or informal leave (pass) status. Applicants for enlistment in the Army and selectees also are authorized necessary civilian medical care at the expense of Army funds while they are being processed for enlistment or induction into the Army. Payment for civilian medical expenses incurred by Army personnel who are absent without leave is not authorized. Any obligations resulting from civilian medical care to Army personnel who are absent without leave are the responsibility of the Army individual concerned.

Normally, civilian medical care for Army personnel is authorized only when there are no other federal medical treatment facilities available. First aid or emergency treatment is authorized at any time, notwithstanding the proximity of Army or other federal medical treatment facilities. Emergency medical care may be defined as that required to save life, limb, or prevent great suffering. Surgical operations should not be performed without prior approval of military authorities, unless indicated as an emergency procedure. Elective medical treatment in civilian medical treatment facilities or by civilian physicians will not be authorized, as Army funds cannot be used for payment of these services.

Due to limitation of funds available, medical care of dependents of military personnel from civilian sources, at Army expense, is not authorized. Dependents of military personnel may obtain available medical care at Department of Defense medical facilities only. Any obligations resulting from civilian medical care to dependents of military personnel are the responsibility of the dependents concerned or their sponsors.

As a general rule, the local military commander will furnish the civilian medical agency with prior written authority for ordinary medical care to Army personnel under his jurisdiction. In such cases prior arrangements with the civilian medical agency will be made by the individual or by a proper military authority. For emergency patients treated without prior written authorization the surgeon of the nearest military command should immediately be notified by the civilian medical agency, giving the individual's name, organization, nature of illness or injury, and statement of the practicability of transfer of the patient to an Army or other governmental hospital. The civilian agency or physician then will be advised without delay by the appropriate military authorities as to procedures to be followed.

Bills for authorized medical care and treatment of Army personnel should be submitted to the commanding officer of the organization to which the patient belongs, or to the military authority who provided the authorization for the medical service. If the location of these individuals is not readily known or if such military commanders authorizing treatment have moved to another station, bills for medical services rendered should be submitted to the military authorities listed below according to states.

For Connecticut, Maine, Massachusetts, New Hampshire, New Jersey, New York, Rhode Island, and Vermont submit bills to the Surgeon, First Army, Governors Island, New York.

For Delaware, Kentucky, Maryland, Ohio, Pennsylvania, Virgina, and West Virginia submit bills to the Surgeon, Second Army, Fort George G. Meade, Md.

For Alabama, Florida, Georgia, Mississippi, North Carolina, South Carolina, and Tennessee submit bills to the Surgeon, Third Army, Fort McPherson, Ga.

For Arkansas, Louisiana, New Mexico, Oklahoma, and Texas submit bills to the Surgeon, Fourth Army, Fort Sam Houston, Texas.

For Colorado, Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, North Dakota, South Dakota, Wisconsin, and Wyoming submit bills to the Surgeon, Fifth Army, 1660 E. Hyde Park Blvd., Chicago 15, Ill.

For Arizona, California, Idaho, Montana, Nevada, Oregon, Utah, and Washington submit bills to the Surgeon, Sixth Army, Presidio of San Francisco, Calif.

For Washington, D. C., submit bills to the Surgeon, Military District of Washington, Washington 25, D. C.

The bill should show the full name, rank, and service number of the patient, place, and inclusive dates of treatment, diagnosis, and charges, all itemized separately. The duty status of the patient at the time of illness or injury also should be shown, such as duty, leave, or pass. Payment will be expedited if the following certificate is typed on the bill and signed:

> "I certify that the above charges are correct and just; that payment therefor has not been received; that the services were necessary in the care and treatment of the person named above; that the services were rendered as stated; and that the charges do not exceed those customarily charged in this vicinity."

______________________ (Signature of Payee)

______________________ (Title or Capacity)

Further information concerning this matter may be requested of the military surgeons at the above addresses or from the Surgeon General, Department of the Army, Washington 25, D. C. Any difficulties experienced should be called to the attention of these Army authorities in order that this program may render the American soldier the prompt and adequate care and treatment to which he is entitled.

DEPARTMENT OF DEFENSE

Dr. Lovelace to Head Medical Policy Council.—Appointment of Dr. W. Randolph Lovelace II as chairman of the Armed Forces Medical Policy Council, effective July 1, was announced May 8 by George C. Marshall, secretary of defense. Dr. Lovelace succeeds Dr. Richard L. Meiling, whose resignation becomes effective June 30. Dr. Lovelace resides in Albuquerque, N. M., where he is head of the section on surgery and a member of the board of governors of Lovelace Clinic. During World War II he served with the Army Air Force, advancing from the rank of major to that of colonel. He was awarded the Distinguished Flying Cross, the Air Medal and three combat stars, the Legion of Merit, and the Army Commendation Ribbon. In 1945 he was presented the Royal Order of the Sword by the king of Sweden.

He has served as surgical consultant for a number of hospitals and two commercial airlines and was appointed a member of the Armed Forces Medical Policy Council when it was established on January 2, 1951. He received an A.B. degree from Washington University, St. Louis, in 1930; an M.D. at Harvard University in 1934; an M.S. in surgery at the University of Minnesota in 1939, and later was graduated from the School of Aviation Medicine, Randolph Field, Tex.

Dr. Lovelace is a diplomate of the American Board of Surgery, a fellow of the American Medical Association, the Institute of Aeronautical Sciences, and the Aero Medical Association, is affiliated with the University of Colorado Medical School as a lecturer in physiology, has contributed numerous papers to medical journals, and was co-winner of the Collier Trophy Award in 1940.

FOREIGN LETTERS

BELGIUM

International Congress on Hospitals.—The Seventh International Congress on Hospitals will be held in Brussels July 15-21, 1951, under the chairmanship of René-Sand. The Congress on Hospitals, the last of which was held in Groningen in 1949, is usually attended by hundreds of directors of public services, men and women active in charities, directors of hospitals, physicians, nurses, social workers, architects, engineers, and technicians. The congress will be devoted especially to hospital problems concerning chronically ill patients and old people. The congress will state its principles and define the outlines of its work. A joint report will be presented at the opening session by Dr. E. M. Bluestone, former director of the Montefiore Hospital in New York, and by Dr. Pierre Delore, professor, Faculty of Médicine, Lyon. The four study sessions will be held simultaneously; problems concerning chronic disease will be discussed.

Infant Mortality in Belgium.—Professor Garot of the University of Liège published in *Bruxelles-Médical* an article on work done to decrease the infant death rate. Infant mortality has greatly decreased in Belgium. From 1935 to 1939, the recorded death rate was between 7.85 and 7.25%; the rate decreased to 5.03% in 1948 and to 4.77% in 1949. This reduction reclassifies Belgium as a country with a low infant death rate. However, the leading countries are still far in advance of Belgium; the rate in Holland in 1948, for example, was only 2.8%. Of a total infant death rate of 6.67%, calculated in relation to the living newborn infants, the death rate was 2.64% the first month and 4.03% during the following 11 months. Consequently, neonatal mortality represents 39.6% of the total infant mortality. Deaths occurring between 1 and 6 months of age represent 45.6% of the mortality for the first year, while mortality between 6 and 12 months is only 14.8% of the total.

In order of importance, the causes of death are listed as follows: (1) premature birth and congenital debility (35.14%), (2) diseases of the respiratory apparatus (17.20%), (3) specific acute and chronic infections (13.08%), (4) diseases of the digestive tract (10.60%), and (5) miscellaneous causes (23.59%). Most unavoidable deaths occur in the first days or weeks of life and are mainly due to trauma and malformation. There is a high incidence of death due to premature birth or congenital debility during the first month. Death from respiratory disease reaches a clearly defined peak between 3 and 9 months of age, in which period one-third of the total deaths occur. Death by specific infection follows an increasing curve with age, but there is an increased incidence after the age of 7 months.

The influence of seasons is definite. Between 1 and 12 months of age, infant mortality reaches a maximum during the first three months of the year and drops to a minimum during the third quarter of the year. The highest incidence of respiratory diseases occurs in the first quarter and the lowest incidence in the third quarter of the year. The peak of specific infections is reached during the first quarter of the year. The lowest incidence of digestive diseases is recorded during the first quarter and the highest during the third quarter of the year.

Fetal anoxia is an important cause of neonatal mortality. Experience has proved, in fact, that it is the diminished oxygen supply to the fetus that most frequently causes accidents leading to stillbirth and to neonatal mortality. Anoxia is a main factor or an aggravating factor in about 50% of the cases of early death. The author concludes that, under the present circumstances, it is not possible to hope to reduce in the coming years to less than 1.5% the mortality of infants between the ages of 1 and 12 months.

Medical Examination of Students.—The free University of Brussels has created a service of preventive medicine, and *Bruxelles-Médical* has just published the first results of their activities during 1949-1950. During the year, 3,821 young persons have been screened by roentgenography, among whom 63 (1.3%) underwent a more thorough examination. Forty-three of the latter group (1.1%) were re-examined, and 5 (0.3%) were found to have an active tuberculous process. This proportion agrees with those reported by other universities. The results of these examinations stress the significance of preventive medical examination. In general it calls the students' attention to weak points in their health. In some particular cases, which were fortunately limited, it has permitted the early recognition and prompt treatment of students with tuberculous lesions.

Cancer of the Heart.—A report of a rare condition was presented at the Belgian Society of Cardiology by Courtoy and Potvliege. An elderly woman showed cardiac decompensation (of right ventricular type). Necropsy disclosed a large heart (825 gm.) a blood-stained pericardiac effusion, and a tumor almost completely destroying the right ventricle. Microscopic examination revealed the reticulosarcomatous nature of the tumor. There was no bundle branch block demonstrated by the electrocardiogram, despite tumor involvement of the terminal portion of the right division of the bundle of His.

Campaign Against Sleeping Sickness in the Belgian Congo.—An important contribution to the fight against sleeping sickness is presented in the recent report of the Central Committee for Medical Services of the Colony. Excellent results were obtained during the last year through the institution of prophylactic treatment with pentamidine® (4,4-[pentamethylenedioxy] dibenzamidine). In 1950, new cases of trypanosomiasis registered totaled 7,609, compared with 9,873 in 1949 and 11,080 at the end of World War II.

ITALY

Chronic Laryngitis.—Prof. Ernesto Pallestrini, recently appointed director of the otorhinolaryngological clinic of the University of Genoa, lectured on chronic laryngitis. Functional laryngeal changes occur during treatment with estrogenic substances. Allergic manifestations, such as the edema of the laryngeal tissues and of the glottis with dysphonia and dyspnea, are now better recognized. Some pathological conditions of the laryngeal mucosa attributed in the past to neuroarthritism and to hormone dysfunction are now known to be due to vitamin deficiencies. Endocrinology has contributed important information on, for example, the interrelation of the larynx and the adrenals and of the sex hormone dysfunctions that cause laryngeal dysfunctions.

According to the speaker constitutional conditions are of fundamental importance in maintaining or aggravating, but never determining, laryngitis. In catarrhal laryngitis, clinical observation aids in establishing the presence and the prevalence of epithelial injuries, injuries of the connective tissue, muscular lesions, and nervous lesions. The predominance of one of these over the others determines the particular clinical form. Among all these, the best known are the epithelial lesions, because they do not present difficulty in visualization; however, on microscopic examination, one becomes convinced that there are also important alterations of the underlying connective tissue. With respect to laryngeal cancer, Professor Pallestrini believes that inflammation of the laryngeal mesenchymatous tissue can constitute a precancerous condition.

The items in these letters are contributed by regular correspondents in the various foreign countries.

Electrochemography of the Heart.—At a meeting of the medical academy Filippo Pacini in Pistoia, Professor Pozzi discussed electrochemocardiographic equipment, consisting of the roentgenologic apparatus, the photoelectric cell with electronic multiplication, the fluorograph, and the electrocardiograph. The speaker supported Professor Luisada's concept that a phonocardiograph, instead of the carotid or the jugular pulse, may be used for timing. He explained the fundamental principle on which electrochemography is based, the different physiological phases that occur, the significance of the tracings, and the principles to be followed in reading them.

An experimental session followed in the roentgenologic laboratory, and the speaker, in cooperation with Professor Romagnoli, demonstrated the procedure of mounting the photocell. Comparing a series of tracings obtained according to the methods of Lianminot and Luisada with the tracings obtained with the most modern electrochemograph, Professor Pozzi showed how the three types of tracings (venoatrial, ventricular, and arterial), although identical in fundamental characteristics, have been enriched in details.

International Radiomedical Center.—Prof. Guido Guida, President of the International Radiomedical Center, discussed the aid given by the center during the year 1950 to seamen aboard Italian and foreign ships in the Mediterranean Sea. The center has established a short-wave radio, which operates 24 hours a day, with broadcasts at fixed hours. It has also organized a course of elementary radio medicine for captains of ships. The center broadcasts a medical program dealing with subjects of interest to the seamen, especially with the problem of nutrition and of human pathology in the tropics. At present it is studying the possibility of extending the radio medical assistance to passengers of long-distance air lines. Sixteen surgical and 198 medical patients were treated during the year 1950.

BRAZIL

Acute Appendicitis in Children.—Dr. Primo Curti, of Hospital das Clinicas, São Paulo, reported the analysis of 91 cases of acute appendicitis in children under 12 years. The diagnosis was confirmed in all cases by examination of the appendix and the peritoneum. The author's cases were compared with the well-known cases of Hudson and Chamberlain, Scott and Ware, Stone, and Boyce, in the American medical literature. The 91 cases were divided as follows: catarrhal 26 (28.6%), fibrinous 9 (9.9%), gangrenous 10 (11.0%), hyperplastic 7 (7.6%), suppurated 13 (14.3%), and perforated 26 (28.6%). The last two types, which comprise the severer forms, represent 42.9% of the total, which does not differ significantly from the figures for the American authors (Hudson and Chamberlain, 44%; Scott and Ware, 44.4%; Stone, 44.9%, and Boyce 37.2%). The same may be said about the sex distribution, as the percentage of male patients is practically the same for all the series of patients (Curti, 54%; Scott and Ware, 59%; Stone, 55%, and Hudson and Chamberlain, 34%). The duration of hospitalization averaged 5.3 days in the simple, catarrhal cases, as against an average of 11.7 days for the remaining cases.

Pulmonary Lesions in South American Blastomycosis.—Pulmonary lesions are now known to be relatively frequent in South American blastomycosis, contrary to reports of earlier authors who studied the disease without the help of routine x-ray examinations and autopsy of the lungs. A. Fialho, in his pathological study of the pulmonary involvement of the disease, published in 1946, stressed the paucity of symptoms and the absence of pain, dyspnea, hemoptysis and high fever, pointing out that a slight cough and low fever are in general the only clinical symptoms of such localization. In a recent study of South American blastomycosis, Carlos S. Lacaz, of the department of microbiology and immunology of São Paulo University, reports the result of x-ray and sputum examinations in 35 cases with the discovery of pulmonary involvement in 20 (57.1%). An important point was particularly studied by Lacaz: Does spontaneous regression of a blastomycotic pulmonary focus occur? In 1946, A. Fialho presented pathological proof of spontaneous remission, such as that which occurs in other pulmonary mycoses, particularly coccidioidal granulomatosis. It is known that in some fungous infections endemic in some sections of the United States, most humans can spontaneously overcome the infection. In such instances, the patients are sensitive for a long period to products of fungi known as coccidioidin and histoplasmin and respond positively to cutaneous tests with these substances. With respect to South American blastomycosis, it has never been proved that a subject with a positive reaction to paracoccidioidin has had a "slight pulmonary infection" without having the "disease." The slight pulmonary lesions—a kind of primary blastomycotic complex—might be calcified, regress, or become generalized. Lacaz, in a preliminary survey of 330 patients, gave intradermal injections of paracoccidioidin in a Smith medium and obtained 26 positive results (7.8%). Results of radiologic examination of the lungs of these patients were normal, and Paracoccidioides brasiliensis was not found. A new series of tests is being performed with diluted paracoccidiodin, in order to eliminate false positive reactions and cross reactions with another mycosis.

Death of Dr. G. Paula Souza.—Dr. Geraldo Paula Souza, dean of the school of hygiene and public health, São Paulo University, and permanent delegate of Brazil to the World Health Organization, died recently, at the age of 62. He studied medicine in Switzerland and Germany and public health at Johns Hopkins University, and commenced his teaching career as assistant to Dr. Darling, who was, from 1918 to 1922, professor of hygiene at São Paulo University. From 1922 to 1927, Dr. Paula Souza was director of the São Paulo state department of health, where he introduced modern methods of public health administration. He was the founder of the São Paulo Institute of Hygiene, which a few years ago was transformed in a School of Hygiene and Public Health with the cooperation of the Rockefeller Foundation. In 1945, Dr. Paula Souza, one of the members of the Brazilian delegation to the San Francisco conference, was the most ardent advocate of the creation of the World Health Organization, and was the author of the proposal to include the "right to health" in the United Nations charter. His death is a loss particularly to the public health field in Brazil.

ECUADOR

Yellow Fever.—Yellow fever disappeared from Ecuador for many years after the campaign against the disease, which was carried on under the direction of Dr. Noguchi, several years ago. Recently the disease reappeared in a municipality 100 km. from Esmeraldas City, in the mountains in the northeast part of the country. About 50 cases of the disease, identified as the jungle form of yellow fever, occurred. A campaign of vaccination against yellow fever was successfully completed. The authorities state the danger is now over.

Maternity Hospital in Quito.—The Isidro Ayora maternity hospital was opened on May 26. It is named for the greatest obstetrician of Ecuador. The hospital, the construction and equipment of which are very much up-to-date, occupies a total area of 7,344 square meters, with a capacity of 210 beds and a space of 40 square meters per bed. It was equipped by donations from the United States of America and the United Nations. The new maternity will function the first year on a budget of 1,906,000 sucres under the direction of an administrative council made up of representatives of the Ministry of Public Aid and Social Assistance and of the Cooperative Service of North America. Dr. César Jácome, head of the old maternity hospital and director of the school of obstetrics of Central University, was appointed director. The president of the republic, the authorities of the state, and the members of the Cooperative Service of North America were present at the opening ceremonies held in May, during which Dr. Maurice Pate, executive director of the UNICEF, received a medal for services given to Ecuador.

CORRESPONDENCE

THE GENERAL PRACTITIONER

To the Editor:—I agree with the statement by Dr. Edward P. Lehman in the May 19 issue of The Journal that the closed staff of the hospital definitely resulted in an improved quality of surgical performance and there is no reason why those procedures requiring a definite and acquired amount of skill should be open to an ill-trained man. Unfortunately, this closing of hospitals did not stop at surgery. It has gradually increased to such an extent that only board men in some larger cities have access to the staff of hospitals, and in many hospitals, if an individual has maternity privileges, he is not permitted to bring his medical cases in. If he has pediatric privileges, he may not bring his gynecological patients in. So, far from being the ideal set-up, it has gradually served to eliminate the hospital practice of an all-round family doctor and concentrated it in the hands of those who profess a specialty. The reaction of the public has been, "If my doctor cannot take care of my child as well as me, what kind of a doctor is he?" And while it may be unwise to believe that the closing of hospital staffs throughout the country was motivated by selfishness alone, it is not unusual to find a newcomer in a community with restricted privileges, while those men who have resided in the community over a long period of years have unlimited privileges despite inadequate training. It is well known that in many areas cliques of doctors do restrict the privileges to their select few.

I greatly fear that many of the surgical procedures which are looked on by the surgeon as requiring a great deal of technique in reality do not. Many general practitioners are forced to do hemorrhoidectomies in the office because the surgical staff will not give him these privileges. Yet these same hospitals may permit him to deliver a baby, though the mortality and morbidity to both mother and infant are infinitely higher than may be expected from hemorrhoidectomy. Many a general practitioner is forced to do a diagnostic dilation and curettage in his office because the privilege of doing them in the hospital is restricted to the surgeon.

I have an x-ray in my office as a matter of service and convenience, and my good friend the radiologist aids me and has never accused me of trying to usurp his specialty. I have an electrocardiogram for the same reason and my friend the internist aids me without accusing me. Yet, I have no desire to be either a radiologist or a cardiologist. Why shouldn't the surgeon offer me the same courtesy and assistance? Many of us have no surgical aspirations whatsoever, but we do feel that certain surgical procedures can and should be done by the family doctor. As general practitioners who are endeavoring to keep abreast of the practice of medicine, the majority of us feel that we know our limitations, that we have no desire to encroach upon someone else's territory, that we place the welfare of the patient above all else, that we have an unlimited belief in the future of general practice, or we would not be doing it.

If the system of closed staffs and hospitals were fair and just, then the plan of the American Academy of General Practice for General Practice Staffs would not be necessary, but the plan is approved by the American Medical Association, the American College of Surgeons, and the American Hospital Association. The inference, then, is that somewhere between the hogwash of the ivory-towered altruist and the grasping of the unscrupulous worker (either general practitioner or specialist) lies the fundamental truth: that both specialist and general practitioner need a place in the medical sun and someday the pendulum may come to rest.

Mount Holly Springs, Pa.

SCHEDULES OF ANTIBIOTIC ADMINISTRATION

To the Editor:—Your editorial on "Schedules of Antibiotic Administration" in the April 21 number of The Journal appears to me to be confusing and to neglect consideration of most important evidence available on the subject. I cannot agree that any uncertainty as to the most effective dosage schedule of antibiotics will be resolved by conclusive information "as to whether the mechanism of their action in vivo is the same as that in vitro or whether host factors may supervene to augment and to supplement their direct bactericidal effect." Neither do I follow the reasoning that leads to the conclusion that "the concentration of penicillin at the focus of infection should *probably* be maintained at the maximally effective level" (italics mine). Instead of attempting to solve the problem of the most effective dosage schedule of penicillin by speculation and reasoning from extraneous data as to its action in vitro, would it not be better to heed old John Hunter's advice to Jenner, ". . . but why think? Why not try the experiment?" In fact, in the third paragraph of your editorial, which completely contradicts the "probable" conclusion arrived at in the second paragraph, it is admitted that Hunter's advice has been taken by some bold souls: ". . . clinical experience has shown that many infections can be adequately controlled by intermittent treatment, with long penicillin-free intervals."

Although these findings refute the belief that a constantly maintained critical concentration of penicillin is essential for satisfactory therapeutic response, they do not permit decision as to the relative effectiveness of frequent or widely spaced administrations of the drug. This decision will be made neither by consideration of speculations on in vitro data nor by studies in severely ill patients. We can, however, set up rigidly controlled experiments in animals which should help in a decision. We can judge most effective therapy in our animal experiments as that requiring the smallest total dose of penicillin to produce a stated curative result. In patients, it is not easy to define the criteria that should be used in determining the most satisfactory or most effective dosage schedule. The first requirement should be the cure of all cases of infection or attainment as near as possible to that ideal. In addition, the number of toxic reactions and the discomfort and inconvenience to the patient must be considered. The cost of and the requirement of the doctor's and the nurse's time in administering the treatment schedule might then be taken into consideration.

The concept of the necessity of a maintained concentration of penicillin in the blood for effective treatment appears to have been a transfer by analogy from therapy with the sulfonamides. Jawetz (*Arch. Int. Med.* **77**:1 [Jan.] 1946) showed that, where measurable blood concentrations persisted for only one hour after injection of penicillin, the depression of bacterial population in a streptococcic infection of mice persisted for at least eight hours. White and his co-workers (*Proc. Soc. Exper. Biol. & Med.* **67**:199 [Feb.] 1948) and Zubrod (Bull. Johns Hopkins Hosp. **81**:400 [Dec.] 1947) studied various schedules of penicillin dosage against a hemolytic streptococcic infection of mice and found that the survival rate was not affected by the number of fractions into which the total dose was divided nor by the interval between doses. Gibson (*Proc. Soc. Exper. Biol. & Med.* **67**:278 [March] 1948) found that the total daily curative dose of penicillin administered to mice infected with pneumococci was the same whether injections were made at 12 or at three-hour intervals. Schmidt and associates (*J. Pharmacol. & Exper. Therap.* **96**:258 [July] 1949) showed that the cure of rats infected intraperitoneally with pneumococci can be accomplished by the administration of penicillin at either frequently spaced or at widely spaced intervals. With a treatment period of 96 hours, two, four and eight-hour dosage schedules were essentially equal in effectiveness, and each of these regimens was more effective than the 12 or 24-hour schedules. With procaine penicillin, injection at 24-hour intervals was only one-fourth as effective as aqueous penicillin at two, four and eight-hour intervals. The data showed that sustained plasma concentrations of penicillin are not at all necessary for a maximum therapeutic response.

In a further study of lobar pneumonia produced by the same Pneumococcus in the rat, Schmidt (personal communication) has found that 12 doses of penicillin at eight-hour intervals are more effective or take less total penicillin to cure than either 24 doses at four-hour intervals or 48 doses at two-hour intervals. Although Eagle has been the main proponent of the necessity of maintaining an effective concentration of penicillin in the blood for most effective therapy, in a recent paper (*Am. J. Med.* 9:280 [Sept.] 1950) he presents data on experimental infections which do not support this opinion. In a pneumococcic infection of mice and a streptococcic infection of rabbits, his data show that, "when with a fixed total number of penicillin injections the interval between them was progressively increased, the dosage necessary for cure at first decreased to reach a minimum but thereafter again increased." Miller and co-workers (*Proc. Soc. Exper. Biol. & Med.* 74:62 [May] 1950) using different dosage schedules of penicillin in the treatment of a penicillin-resistant S. typhosa infection in mice, found that the total amount of penicillin necessary for cure increased as the daily dose was split into more and more injections.

The last experimental investigations on the dosage schedule of penicillin mentioned above make one wonder whether intermittent dosage with aqueous penicillin may not be more effective than continuous dosage or the use of a depository preparation in many human infections. In fact, recent experience with the treatment of pneumonia with aqueous penicillin at 12-hour intervals suggests that this may be so.

Streptomycin, when first introduced into clinical use, was given every few hours from analogy to the dosage schedule of the sulfonamides. Zubrod found (*Bull. Johns Hopkins Hosp.* 82:357 [March] 1948) that, in the treatment of mice infected with Klebsiella pneumoniae with streptomycin, there is no significant difference in results with dosage schedules of four-hour intervals or of eight-hour intervals. Feldman and Hinshaw (*Am. Rev. Tuberc.* 55:428 [May] 1947), in a study of tuberculosis in guinea pigs, found that the administration of streptomycin at frequent intervals was not essential for successful therapy.

E. K. Marshall Jr., M.D.,
Professor of Pharmacology and
Experimental Therapeutics, The
Johns Hopkins University,
Baltimore.

[Dr. Marshall's letter was referred to the writer of the editorial, whose comment follows.—Ed.]

It seems to me that Dr. Marshall has missed the essential point of the editorial, which was that the therapeutic efficacy of penicillin appears to be measured by the total time, *not necessarily continuous,* for which it remains at effective levels at the focus of infection. The editorial did not even suggest that "a continuously maintained critical concentration of penicillin is *essential* for satisfactory therapeutic response" (italics mine), nor have I made that point in my own papers. All the data in hand indicate that penicillin cures infection primarily because it kills bacteria and that its efficacy is measured quite simply by the total time for which it is present in effective concentration. I am not clear as to just what Dr. Marshall is suggesting as an alternative thesis; but all the points he raises in his letter are wholly consistent with the editorial, and every one of the papers he cites was considered in detail in the two papers on which the editorial was largely based (*Am. J. Med.* 9:280 [Sept.] 1950; *Ann. Int. Med.* 33:544 [Sept.] 1950).

Dr. Marshall's letter raises three general points as militating against the therapeutic importance of the penicillin concentration:

1. Animals or human beings may be cured by treatment schedules in which there may be long penicillin-free intervals. This point was considered in detail in both of the papers cited above. As there shown, and as stated in the editorial, an intermittent schedule will be effective provided that the surviving bacteria are not given sufficient opportunity between injections to recover and remultiply: but it owes its activity to the time for which penicillin remains at effective levels. This was clearly shown in both of these papers; in pleading for experimental data, Dr. Marshall appears to have overlooked the data there given. Similarly, the fact that a fixed number of injections may be more effective if given, for example, every 4 hours than if they are given every hour was shown to follow from the longer aggregate "penicillin-time" in the former instance.

2. The fact that experiments can be set up in which a single injection is more effective than multiple injections is quite simply explained by the fact that, in an infection which is rapidly cured by penicillin (e. g., mice freshly inoculated with small numbers of pneumococci or streptococci), subdividing the single curative dose may reduce the dosage per injection to the point that an effective level is no longer provided. This is, however, a specific case which has no general validity. If the infection is such that a relatively long "penicillin-time" is required for cure, the curative dose on the divided schedule may be and usually is a minute fraction of that necessary when given in a single injection. With the same organism and with the same host, one may obtain both types of result, depending on the size of the inoculum and the age of the infection. In all cases, however, the therapeutic activity is determined by the aggregate time for which penicillin remains at effective levels. Here again, the experimental data are perfectly clearcut.

3. The time for which penicillin remains at *measurable* concentrations in the serum bears no necessary relation to the time for which it remains at *effective* levels at the focus of infection. With some organisms, susceptible only to high concentrations of penicillin, the duration of the therapeutic effect may be much less than the time for which penicillin remains at measurable concentrations; while with highly sensitive organisms, requiring less than, for example, 0.01 microgram per cubic centimeter, effective levels and a therapeutic action may persist for a much longer time than a "measurable" serum level of, say, 0.03 microgram per cubic centimeter. One can cure syphilis in rabbits with dosages of penicillin which never provide measurable serum concentrations but which do provide in the tissue fluids the effective level of 0.002-0.005 microgram per cubic centimeter.

I can only repeat that all the data in hand, including the evidence cited by Dr. Marshall, indicate that the therapeutic activity of penicillin is determined by the total time, not necessarily continuous, for which it remains at effective levels at the focus of infection. Depending on the concentrations necessary and the time required for cure, a single injection may prove more effective or far less effective than the same dose divided into multiple injections; and intermittent therapy, with long penicillin-free intervals, will be just as effective as sustained concentrations, provided that the bacteria are not given an opportunity to recover and remultiply.

MISMATCHED BLOOD TRANSFUSION

To the Editor:—In The Journal of March 31 (145:978) there is a clinical note on successful treatment of mismatched blood transfusion by alkalinization with sodium bicarbonate. The authors consider that this treatment is not generally known, but surely it should be known by now, as it was used for blackwater fever (where there is similar hematin blockage of renal tubules) some 30 years ago. We stressed its value in mismatched blood transfusion in a paper written in 1925 (*Brit. J. Exp. Path.* 6:247).

COUNCIL ON INDUSTRIAL HEALTH

DISASTER BLUEPRINT FOR THE INDUSTRIAL PHYSICIAN

The following recommendations apply to those industries of sufficient size to justify a civil defense industrial health program. If a plant does not feel able to participate because of size, location or other reason, the local civil defense administration should be consulted for advice and assistance. Each program must be tailored to meet the needs of the individual plant and integrated with the community civil defense planning.

There are two major phases of planning: (1) specific disaster control preparations by industrial physicians, and (2) general disaster control preparations by industrial physicians. It must be emphasized that both phases start *now* and proceed simultaneously.

The following should be done in preparation to make disaster effects less disabling to the civilian population in industry.

I. SPECIFIC DISASTER CONTROL PREPARATION BY INDUSTRIAL PHYSICIANS

In case of disaster, industrial management and the medical director must be prepared to meet the emergency. This can be accomplished by organizing and mobilizing a plan now, and integrating it with the community civil defense organization. Local conditions will undoubtedly influence certain details; however, the basic essentials as outlined below should act as a fundamental framework for all industrial health service planning in preparation for effectively handling a major disaster situation.

A. *Scope of Medical Service.*—The industrial medical service should be set up to act as a casualty clearing station in case of disaster so that it can cooperate with the community emergency first-aid services as outlined by the Federal Civil Defense Administration.[1] In event that the disaster directly involved a given industry, the plant medical service would administer first aid to the casualties. This would be limited primarily to splinting of fractures, controlling hemorrhage, treating shock, emergency treatment of burns, and relieving of pain. The seriously injured would then promptly be transported to designated hospitals. Next, the ambulatory casualties would be treated and sent home or to a designated hospital, depending on the severity of the injury.

The following suggestions delineate industry's role in disaster planning under four specific circumstances:

1. When a given industry is involved but not completely annihilated, and with a functioning medical unit in the plant at the time.
2. A given plant is involved as above, but a major portion of its medical staff is outside the plant at the time.
3. A given plant and its medical facilities are left intact but adjacent areas, including the homes of some of its workmen, are involved.
4. The target area is at a considerable distance from the plant in question.

Obviously, the duties of a plant's medical personnel will differ not only under each of the above circumstances, but also will vary with the size of the plant, the kind of medical service, and its relationship to a primary or secondary target area. All of these factors must be taken into consideration in planning the most effective utilization of industrial medical services in the event of disaster.

First, as to the organization of a plant medical service to meet disaster, the following suggestions are offered:

1. Every industry should draw up tentative plans for the organization of its medical defense program and submit them to its local Civil Defense authority for approval and coordination with local Civil Defense plans. Responsibility should rest with the plant's medical director who will coordinate these plans with the plant's entire defense program as well as that of the community. Plants without the regular services of a physician should contact the local Civil Defense authorities for advice.
2. Every plant with a full-time industrial physician in charge of the medical service, and particularly those which are isolated or spread over sufficient area to cause transportation to become a problem, should organize mobile first-aid units patterned after the recommendations made by the Federal Civil Defense Administration in its manual, "U. S. Civil Defense, Health Services and Special Weapons Defense."[1] These units should be capable of moving into the stricken area quickly to support the local Civil Defense units. These mobile first-aid units are in addition to the fixed medical services in the plant.
3. Smaller plants everywhere should pool their medical resources and support the organization of similar mobile units in coordination with the community Civil Defense plans.

The ability to work smoothly as a team should be fostered by frequent trial runs under simulated disaster conditions, both separately and in conjunction with local air raid drills.

The following suggestions are offered as a basis for planning the plant's medical services under the four specific circumstances mentioned above:

1. It should be recognized that should any part of a plant be involved in a disaster, and even if the medical personnel and its supplies are spared, which is unlikely, the plant's own medical staff would be wholly unable to care for the large number of casualties among its own employees. On the other hand, the rest of the community is faced with a similar overwhelming of its medical facilities for a period of time before it recovers from its initial shock and help begins to arrive from surrounding communities. Assuming that casualty collecting stations have been designated beforehand and that there is no complete breakdown of the transportation system, the primary responsibility of the plant's medical unit will be to evacuate its casualties to the clearing stations as quickly as possible. Therefore, planning should be based on providing for the inspection and classification of all casualties so that the transportation system is not bogged down with dead and dying, and so that the limited facilities of the medical department are used to greatest advantage. In general, it will probably be impossible to do more than control gross hemorrhage, relieve pain, and apply only such dressings and splints as are absolutely essential to permit the evacuation of the patient. If for any reason the casualties cannot be evacuated, the fate of the seriously injured will depend on the ingenuity and resourcefulness of the medical personnel and the speed with which essential medical supplies can be brought into the plant.
2. When a majority of the medical personnel is outside the plant at the time that disaster strikes, as might happen in a night attack, the problem is mainly one of planning for the staff to proceed to the stricken plant as quickly as possible. The smaller plants will, no doubt, depend largely on the community defense program for relief, but the larger plants with well-organized mobile first-aid stations adequately equipped and stored at a safe distance from a primary target area, should be expected to move quickly into the area. Although such units should be primarily responsible for their own plants, they should be cleared through the Civil Defense control officer who will advise them of the area of destruction, route to be used, and other instructions essential to a coordinated plan of action.
3. When the adjacent community is involved, and after all of the in-plant casualties have been treated and evacuated, the industrial medical service personnel will then be available to move into the involved community area. Whether it does so as

---

This is a special report made by the Subcommittee on Defense of the Committee on Industrial Health-Defense of the Council on Industrial Health, American Medical Association. The members of the Subcommittee are Dr. Charles-Francis Long (Chairman), Bayuk Cigars, Inc., Philadelphia; Dr. Paul Bamberger, Bethlehem Steel Company, Bethlehem, Pa.; Dr. Jean S. Felton, Medical Director, Oak Ridge National Laboratory, Oak Ridge, Tenn.; Dr. Robert H. Flinn, Consultant, Health Office, Health and Welfare Division, Federal Civil Defense Administration, Washington, D. C.; Dr. Irving R. Tabershaw, Director, Eastern Medical Division, Loss Prevention Department, Liberty Mutual Insurance Company, New York, and Dr. J. F. McCahan, Assistant Secretary, Council on Industrial Health, American Medical Association, Chicago.

(*b*) Manual of Industrial Hygiene and Medical Services in War Industries, edited by W. M. Gafafer, Division of Industrial Hygiene, National Institutes of Health, United States Public Health Service, Philadelphia, W. B. Saunders Company, 1943.

a mobile unit or whether each individual is assigned to other units will depend on the organization of the plant medical department and the plan of action drawn up in cooperation with the local Civil Defense authorities. If possible, the plant medical unit should be utilized by Civil Defense as a unit.

As soon as emergency casualty care has been completed in the community, the industrial medical service team should return to the plant to assist in the re-establishment of production. Disaster casualties should go to mobile first-aid stations, fixed casualty dressing stations, or their attending physician for re-dressings until such time as they are given written approval by the attending physician for return to work. They should then clear through the plant medical department unless it is completely overwhelmed by emergency work. Under these circumstances the safety supervisors or foremen should be responsible for screening the employees before they resume work. Even after the injured employees resume work, the industrial medical service may need staff assistance and supplies from the community civil defense administration if they are going to be able to assume after care re-dressings. This will allow the industrial medical service to function effectively to furnish health and emergency service to those employees who are already back on the production line.

4. When disaster strikes at some distance from the plant, it should be expected that every effort will be made to maintain production of essential materials. The plant's medical department should be expected to retain at least a skeleton staff to provide for the essential medical needs of the workmen remaining on the job. The size of this staff should be determined beforehand and all personnel not absolutely essential for a minimal medical force should be dispatched to the stricken area, either as a unit or as part of a unit, depending on the number of medical personnel available for this purpose.

B. *First Aid Training.*—Industrial management should provide first-aid training utilizing the medical service staff, safety department and/or the Red Cross to conduct the courses. The medical director should be in charge of the training and be responsible for designating a number of trained intelligent individuals as instructors who in turn should train additional instructors, depending on the size of the plant. It should be desirable for every employee to receive basic first-aid training. It is the responsibility of the medical director to determine the number of first aiders to be trained, to advise management as to these needs, and to make sure that an adequate number are trained. A minimum of 12 hours instruction should be given each employee. Each employee should be issued a small pocket-size simplified first-aid manual. Employees should be trained to work as a team, but to emphasize also, that with great numbers of casualties, it may be necessary for them to work in pairs or perhaps even individually. The fundamental purpose of first-aid is to prepare the patient for transportation in such a way that he has a chance to get to a treatment center alive and in no worse shape then he started out. No more.

First-aid teams should be established consisting of *six* persons, four of whom are physically capable of functioning as litter bearers. The two remaining members of the team should have advanced first-aid training so that they could act as team captains in supervising the work of all others who are available and qualified to help.

Litters should be provided in the following number as a minimum: [1]

1- 99 employees: 1 litter for each 25 persons
100-499 employees: 1 litter for each 50 persons (minimum 4)
500 or more employees: 1 litter for each 100 persons (minimum 10)

C. *Rescue Squads.*—This is not primarily a responsibility of the medical service. However, its work must be integrated with that of the medical staff so it is important for the two groups to coordinate their planning.

The number of these rescue teams as well as their equipment and training will depend to a great extent on the type, size and location of the plant. They should have basic first-aid training and be familiar with the potential hazards that exist within the plant as well as those that may be present in other industries in the adjacent area. They should receive basic training in the detection and de-contamination of areas affected by chemical, electrical, radiation or biological factors. The rescue squads will have to depend on monitoring teams to advise them regarding entrance into contaminated areas. In a limited number of industries monitoring teams will be established as part of the in-plant defense program; however, in most instances their service will only be available through the local civil defense administration. These monitoring teams should be advised by each plant of its needs and also informed of any hazardous materials or processes that might contaminate the area in case of disaster.

D. *Equipment and Supplies.*—1. Estimated Requirements: Requirement for one mobile first-aid station equipped to treat 500 casualties are shown in Table 4.36 and 4.37, page 57, "Health Services and Special Weapons Defense." [1a] Individual industrial health services can use these two tables as guides in selecting equipment and supplies to fit their needs as determined by size of plant and estimated casualties as determined by the method set forth in Fig. 1.48, page 16, "Health Services and Special Weapons Defense." [1a]

2. Other Equipment: This would include gas masks, oxygen resuscitation apparatus and special types of protective clothing for rescue work. The amount and type of equipment necessary would vary with the requirements of the plant.

3. Expendable Supplies: In plants where industrial medical services already exist, the supplies should gradually be increased not to exceed 20 per cent in excess of normal inventory, and only to include first-aid materials such as dressings and bandages of various types, and not to include plasma and other similar supplies.

Many industries do not have in-plant first-aid or medical services available. The Council on Industrial Health of the American Medical Association has a reprint "The Industrial Medical Department," available upon request, which is designed to act as a guide in developing a medical department in plants of various sizes. Sample floorplans are given and check lists of basic equipment and supplies are enumerated.

Supplies of certain items are already short so that rapid build-up of inventory would seriously affect the availability of current needs. The Civil Defense Administration is planning to stockpile materials on the periphery of target areas which will be moved in as needed. The industrial medical service should depend on this source of replenishing of supplies as needed at the time of disaster. Ambulances and other casualty transports should be used to bring in the supplies on their return trips from the hospitals to the disaster areas.

E. *First-Aid Boxes.*—The number of first-aid boxes should be determined by each plant as follows:

1- 99 employees: 1 box for each 25 persons
100-499 employees: 1 box for each 50 persons (minimum 4)
500 or more employees: 1 box for each 100 persons (minimum 10)

Type of Box: The inside dimensions of the box must afford a total of 540 cu. in. of space, (e. g., 10 in. by 9 in. by 6 in.) to contain the supplies listed below. A box that will resist weather and reasonably rough handling must be used. As metal becomes more scarce, weather resistant masonite, ply-wood and other similar substitutes can be used. A carrying device such as will hold the box and allow it to be slung over the shoulder or carried like a knapsack is essential so that the hands can be left free to facilitate climbing over obstacles which would be present in the disaster area.

Contents of Box: The box should contain:

Triangular bandages	12*
Square yard of gauze mesh folded	2
3 in. by 3 in. gauze pads, individually wrapped	24
2 in. roll bandage	6
Single-edge razor blades	6
Ammonia inhalants	6
Marking pencil	1
Lipstick	1
Identification tags as specified by CDA	6
Safety pins	12

* Minimum.

Replacement supplies should be stored at strategic locations throughout the plant, preferably in shelter areas. It should be kept in mind that clean clothing, yard goods and handkerchiefs make desirable auxiliary dressing supplies. Plants with women employees should bear in mind that the common sanitary napkin makes an excellent and easily applied emergency dressing.

F. *Transportation and Communication.*—Transportation and evacuation facilities must be established within the plant and integrated with the Civil Defense planning in the community.

Communication facilities will include telephone, radio and messengers. In the event of a major disaster, telephone service would undoubtedly be interrupted so that messengers might be shared by the first-aid teams, rescue squads, demolition crews, firemen and others in keeping in touch with the plant central control officer.

II. GENERAL DISASTER CONTROL PREPARATIONS BY INDUSTRIAL PHYSICIANS

A. *Health Services Inventory.*—Make an inventory of industrial health facilities, services and personnel. This would give the civil defense administration an index of industrial health services potential and distribution.

1. Objectives: The purpose of this inventory is to obtain adequate information, whether by means of a questionnaire, inspection or both to permit a more accurate appraisal of the ability of industry's health services to meet the ordinary needs of an industrial population engaged in all-out preparation for defense. Such information is equally essential for an appraisal of industry's readiness for the extraordinary requirements of defense against attack, whether by atomic bomb, guided missile or conventional strategic bombing. Finally, it is necessary for the most effective coordination of industrial and civilian defense efforts and for the pooling of a community's resources in the event of disaster.

2. Scope: The inventory should be sufficiently broad to permit local, state and national defense authorities to access accurately each plant's ability to meet its own defense requirements and still contribute to the pooled resources of the community, the state and the nation. Although specialists in other fields will be needed, and materials and facilities other than medical should be inventoried, this inventory will be limited to medical and closely allied services.

3. Procedures: The following is suggested as essential information although by no means is the list to be considered complete or the possibilities of the questionnaire exhausted.

(*a*) Identification, location, description. This should include the name of the plant, parent company and headquarters, if any, exact location, size in terms of area covered, floor space, number of buildings or some other guide to its size, including present plant population and estimates of the maximum anticipated population based on past experience.

(*b*) Medical department personnel. Personnel should be named and described, and indicated as "on call," "part-time" or "full-time." The exact time spent in the plant by part-time physicians should be noted. The person in charge of the medical department or health services and the person (and title) to whom he or she reports should be indicated. Other medical department personnel to be listed are registered male and female nurses, industrial hygiene personnel, laboratory and X-ray technicians, practical male and female nurses, orderlies, medical secretaries, typists, clerks, ambulance drivers, and chauffeurs if under medical department supervision exclusively (not from motor pool).

(*c*) Hospitals, dispensaries, first-aid stations. The name of the hospital or hospitals to which injured employees are ordinarily taken and the approximate distance of each from the plant gates. State if there is provision made for reserving beds for employees, the number of such beds and the total number of beds in each hospital. Give the number of dispensaries and first-aid stations within the plant, the nominal floor space, number of beds, description of how each is staffed, and the average daily admissions or treatments given in each. State the number of beds or cots available on short notice for use in a catastrophe and whether stored within or outside the plant.

(*d*) Storage of medical supplies and equipment. How much expendable medical supplies are stored in the plant in terms of the estimated time in which they would normally be used? Are additional supplies and/or equipment stored elsewhere for safety? Does the plant maintain its own blood bank? How much blood, plasma, intravenous solutions, if any, are stored in the plant, in a hospital and/or elsewhere? How many litters, blankets, respirators, gas masks, first-aid kits are available in the plant or stored elsewhere? If more than one, are they distributed about the plant, or stored in a central location? Who has charge of distribution and inspection of the above equipment?

(*e*) Health and related services. State which of the following services are provided in the plant dispensaries: major surgery, minor surgery, and reduction of fractures requiring general anesthesia (intravenous or inhalation) or spinal anesthesia, suturing and dressing of minor wounds; first-aid only; pre-employment physical examinations; periodic physical examinations; pre-employment chest x-ray; periodic chest x-ray; x-ray of injured parts; other x-ray service; complete clinical laboratory service; blood typing service; simple urine and blood examinations. Which of the following related services are provided and if not by the medical department, by whom? Training in first-aid, artificial respiration, rescue, gas-mask training, litter-bearing and improvising, radiation monitoring, decontamination, demolition. Are employees trained in first-aid as teams or individually?

(*f*) Miscellaneous. Are dispensaries and first-aid stations provided with auxiliary heating and lighting facilities? Are "bomb-proof" shelters provided? Are they equipped with cots, medical supplies and auxiliary heating and lighting, to be used as clearing stations for casualties?

B. *Consultants.*—The Committee recommends that competent consultants in industrial health and hygiene be available to Civil Defense Administrations wherever organized. They would be responsible for assessing the strength of health services in the various areas through application of the health services inventory. This information would then be tabulated as to classes of industry following the pattern of breakdown already established by the National Safety Council.[2] After the surveys have been completed locally, they should then be centralized for national tabulation. Information thus assembled can function as a yardstick for an individual industry to use in assessing its needs.

All industry should have access to expert industrial health service advice as it relates to disaster planning. This should be available through the consulting service of the civil defense administration.

C. *Immunization.*—The industrial population should understand the need for an immunization program. Cooperation of press, radio, Civil Defense groups, labor unions and management as well as industrial physicians and private practitioners is needed to successfully carry on an immunization program of this scope.

Immunization against small pox, typhoid fever, paratyphoid A and B, and tetanus is urgently recommended.

Influenza and diphtheria immunizations should be administered in areas of epidemic outbreak.

In areas where certain diseases are endemic such as yellow fever and typhus and when the efficacy of immunization has been established, it should be carried out.

D. *Blood Typing.*—This Committee endorses the efforts of the Red Cross and other interested agencies to meet quotas for blood now needed for the Armed Forces and for plasma manufacture. It is a necessary effort and must not be confused with our discussion of blood typing. Regardless of present needs, this Committee strongly urges blood typing in industry *now*, beginning with the employees in large industries in and adjacent to all target areas. The purpose is to discover and tag all "O" class potential donors between 18 and 60 years of age. In this way there will be set up a "walking blood bank" so that without worry concerning storage, viability or erythrocyte freshness, physicians will have at hand immediately a huge pool of available blood carried in the veins and arteries of the "O" group survivors. We know that if disaster strikes any of our industrial centers the need for blood within the first four or five days will be so astronomical that creating this "walking blood bank" is the only answer our Committee can conceive to the solution of the problem.

We would warn those officials in Civilian Defense responsible for providing blood that they must move now to store blood-letting apparatus on the periphery of target areas and set up classes to train nurses, technicians, and possibly even nurses' aides in the techniques of blood collecting.

---

[2] National Safety Council, Chicago.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Sherman Anti-Trust Act in Relation to Medical Society Sponsored Prepaid Medical Care Plan.—The United States filed an action against the Oregon State Medical Society, the Oregon Physicians' Service, and a number of individual physicians to restrain the alleged violation by the defendants of the Sherman Anti-Trust Act. The case was heard in the United States District Court, District of Oregon.

The government contended that the defendants, beginning in about 1936, conspired to restrain and monopolize prepaid medical care in the State of Oregon, and that they did restrain and monopolize the prepaid medical business in the areas in which they operated. The following findings of fact, among others, were made by the trial court.

The Oregon Physicians' Service is a corporation incorporated under the laws of the State of Oregon, having its office and principal place of business in Portland and it furnishes prepaid medical, surgical, and hospital care on a prepaid contract basis. It is sponsored and approved by the Oregon State Medical Society and the great majority of its stockholders and participating physicians are members of that society. None of the defendants, either at any of the times set forth in the complaint or at any other time, have attempted to, or have been engaged in any combination or conspiracy to, restrain or monopolize the business of selling or furnishing prepaid medical care in the state of Oregon or elsewhere or to restrain or monopolize interstate trade or commerce in said business: Prior to 1941, some of the defendants advised doctors not to cooperate with commercial prepaid medical care organizations in certain practices engaged by them, but such action was not the result of any conspiracy or combination or attempt to restrain or monopolize the business of prepaid medical care, but was for the purpose of maintaining the standards of medical practice. Prior to 1941 the defendant Multnomah County Medical Society expelled certain members who were associated with certain types of contract practice and threatened the expulsion of other members so engaged, but such action was not the result of any combination, agreement or conspiracy in restraint of trade or commerce or otherwise; it was for the purpose of maintaining and advancing the standards of medical practice. No other defendant has ever expelled, threatened or incited the expulsion from medical societies of any doctors because of any cooperation in prepaid medical care plans, and since 1941, none of the defendants has expelled, threatened or incited the expulsion from medical societies of doctors cooperating in medical plans other than those sponsored by the defendants. The defendants have formed and promoted certain prepaid medical care plans, but such action on the part of the defendants was not pursuant to any conspiracy, combination or attempt to restrain or monopolize trade or commerce and was not with the intent to drive out, hinder and obstruct commercial prepaid medical care plans operating in the State of Oregon, but it was with the intention to legitimately compete with such commercial medical care plans. None of the defendants at any time has interfered with, or attempted or combined or conspired to interfere with, commercial prepaid medical care organizations in obtaining hospital facilities for their members. None of the defendants at any time has refused to treat patients or caused others to refuse to treat, or combined or conspired to refuse to treat any patients who were members of any prepaid medical care plan, or discriminated against any such patients by reason of such membership.

Oregon Physicians' Service was intended to be an agency, and has in fact been an agency, to provide a prepaid medical care plan in Oregon by a doctor-sponsored group in areas where such a plan had not yet been organized by the local doctors, and in cases where groups of patients live or work in more than one county, and in cases where the local doctors' plan has not yet provided for auxiliary contracts, such as "family contracts" or "individual contracts." Oregon Physicians' Service provides for medical and hospital care, in one form or another, in every county in Oregon. Most of the doctors participating in the local doctor-sponsored plans are also participating physicians of Oregon Physicians' Service. No local plan of prepaid medical care sponsored by doctors of any county has attempted to sell contracts for prepaid medical care in other counties without the consent of the doctors in such counties who would render the services provided in said contracts. The reasons for these policies are, first, that defendants believe that doctors should not attempt to sell the services of other doctors without their consent, and, second, competition between two doctor-sponsored plans in a single county is impractical, since the same doctors must render services under whatever plans are in operation. These policies and the carrying out of these policies have not been a result of any conspiracy or combination in restraint of trade or commerce and have not resulted in restraining or monopolizing the business of selling or furnishing prepaid medical care.

Defendant medical societies are voluntary associations and membership or nonmembership in any of defendant societies has no effect on the privilege to practice medicine in Oregon under state laws. Membership on a hospital staff in Oregon is granted or withheld by the governing body of the particular hospital and has not been granted or withheld from any doctor because of his connection with any prepaid medical care organization, whether such organization was sponsored by defendants or not. No doctor has been deprived of any staff membership in any hospital in Oregon because of his connection with any prepaid medical care organization not sponsored by defendants.

The practice of medicine as conducted within the State of Oregon by doctors of Oregon, including defendants, and the sale of medical services, by doctor-sponsored organizations, as conducted within the State of Oregon, are not trade or commerce within the meaning of Section I of the Sherman Anti-Trust Act, nor is it commerce within the meaning of the constitutional grant of power to Congress "To regulate Commerce . . . among the several States."

Some or all of the defendants have participated in the preparation and promulgation of schedules of fees to govern charges to be made by doctors in the furnishing of medical and surgical care provided in connection with (1) the prepaid medical care plans of Oregon Physicians' Service and other doctor-sponsored prepaid medical care plans in the State of Oregon, and (2) activities of certain governmental agencies, at the request of such agencies. The schedules of fees used in connection with Oregon Physicians' Service and other doctor-sponsored prepaid medical care plans do not themselves necessarily set forth the actual fees to be collected by doctors, but instead determine the relative proportions of the net profits of such prepaid medical care plans, during any given period of time, to be received by doctors for specified medical services. Doctors participating in said plans agree to accept compensation for services based upon a percentage of the amount available for distribution to doctors after deduction of hospital charges and other expenses.

Except in connection with the rendering of services under said prepaid medical care plans or governmental activities, there has been no attempt by any of the defendants to fix or designate fees or charges to be made by doctors in Oregon in the rendering of medical or surgical services. The fixing of fees is a necessary element and of the very essence of all prepaid medical care plans, whether doctor-owned or privately owned, and all prepaid medical care organizations in Oregon, including commercial companies, fix or designate or determine fees for services under or pursuant to or in cooperation with said plans. In the case of doctor-sponsored prepaid medical care organizations, the purposes of these fee schedules are as stated above; and in the case of commercial organizations, the schedule of fees designates either (1) the amounts to be paid for specified services, or (2) the maximum amounts of indemnity to be paid members of or subscribers to said organizations for fees paid or incurred by them for medical or surgical services.

The expression to "take tickets" means that a doctor rendering services to a member of a prepaid medical care plan sends his statement for services to the corporation or other organization owning or controlling said plan, and accepts checks from said organization. There is no present conspiracy, combination, agreement or concert of action among doctors not to "take tickets" of privately owned hospital associations; nor is there any conspiracy, combination, agreement or concert of action among doctors not to accept payment from privately owned hospital associations. The refusal by doctors to "take tickets" of or accept payment from privately owned associations is not boycott.

On the basis of all the evidence, the trial court concluded that none of the government's charges were proven by a preponderance of the evidence. The question, said the trial court, was whether the Oregon doctors in the formation of their own prepaid nonprofit organization, Oregon Physicians' Service, have violated the Anti-Trust laws. As competitors of the privately owned for profit organizations in the same field, have the doctors transgressed the bounds of legitimate competition? I hold that they have not, said the court. The period from 1936 to 1941 was a period when the doctors were trying to find themselves. It was a defensive period. The doctors felt that they were being exploited. They were trying to maintain their professional standards. They felt the doctor-patient relationship was being destroyed. It was a period of groping for the correct position to take to accord with changing times. The doctors sponsored their own prepaid plan and then repudiated it. What the doctors did during this period was not conspiracy. I really doubt, the trial court continued, that the government believed the operations of Oregon Physicians' Service to be monopolistic. Its two chief competitors are tremendously profitable; they have the cream of the business, going only into selected areas, whereas, Oregon Physicians' Service must go everywhere and has many other weaknesses, inheritant cooperative enterprise. I hold, concluded the trial court, that Oregon Physicians' Service is not a conspriacy, but, rather, an entirely legal and legitimate effort by the profession to meet the demands of the times for broad medical and hospital service, eliminating the evils of privately owned concerns, as well as the element of private profit.

Accordingly the trial judge entered an order in favor of the defendants and dismissing the plaintiff's complaint with prejudice.—*United States v. Oregon State Medical Society, 95 F. Supp. 103 (1950).*

Hospitals: Broken Needle Left in Patient's Arm by Nurse.—This was an action by the plaintiff to recover damages for the alleged negligence of nurses employed by the defendant hospital, a private institution operated for profit. From a judgment in favor of the plaintiff, the defendant hospital appealed to the Supreme Court of Mississippi.

The plaintiff became ill with gastritis and was sent to the defendant hospital. Among other treatments which her physician prescribed for her were several injections of glucose into her body every 24 hours. These infusions were given to the plaintiff by nurses employed by the defendant. The glucose was obtained by the hospital in a bottle ready to be administered to the patient. The nurses, when giving this substance to a patient, would use a rubber tube, at one end of which was a hollow metal tube to be inserted through the cork in the mouth of the jug containing the glucose which was then inverted and placed on a stand above the patient. The other end of the rubber tube had a place for a hollow hypodermic needle. The patient's arm would be immobilized by placing it on a board and strapping it down with adhesive tape, after which the needle would be injected into the arm in the cubital area on the inside of the arm near the elbow. After the injection of the needle, adhesive tape would be placed at this point to hold the needle in place and the glucose inserted into the patient's veins by a drip method. After the prescribed amount of glucose had been administered, the nurse would remove the needle, clean it out with a syringe and send it to a central place where it would be sterilized for future use.

After the plaintiff left the hospital, the place on her left arm where these injections had been made continued to be sore, swollen, with a strong, unpleasant odor and great pain. Four days later her physician treated the plaintiff's arm for the infection, and in succession two other doctors treated her. At the time one of these physicians checked her arm she was in another hospital as a paying patient. He testified that the plaintiff was suffering from an infection consisting of a superficial ulcer in her arm and that when he prepared to change the dressing on it he observed an ulcerated part in the cubital area opposite the elbow about the size of a dime. He stated that "on top of the crust of that area was a metallic object" which "was visible when the dressing was removed" and that he "took a pair of little tweezers and lifted off" the crust. The physician then gave this needle to the plaintiff and the broken piece of hollow needle, about ½ in. in length, was introduced as an exhibit at the trial.

The testimony of the plaintiff's witnesses, not disputed, was that the plaintiff had never had, prior to the infusions in the defendant hospital, any trouble with her arm, nor any injections by needles in her arm, and that after being discharged from the hospital the plaintiff had no such injections. The only persons who had made injections by needle into her arm were the employees of the defendant during the time she was a patient in the defendant hospital. The defendant hospital introduced its hospital records and six nurses who had made them and had administered the glucose infusions to the plaintiff. All of them testified that during none of the infusions had they observed a broken needle. They were not able to identify who had terminated one particular infusion, however. They also testified that they had never seen an infusion needle broken.

There was no dispute, said the Supreme Court, that the piece of needle was removed from the plaintiff's arm, and the jury could well have believe that in the month after leaving the hospital the needle had moved to the surface of the ulcer and finally become visible. The other substantiating evidence, the court continued, was enough to warrant a finding that the needle was inserted and broken off in the plaintiff's arm, by an act of the defendant's servants in the hospital, and that either it was negligently broken off in her arm by the defendant's servants or the defendant was negligent in failing to ascertain that the needle had broken there and in failing to remove it or to advise the plaintiff thereof, or both. The defendant argued that there was no direct testimony, by any eyewitness, of the breaking of the needle in the plaintiff's arm. The Supreme Court said, however, that negligence of this type seldom can be proved by such direct evidence. Circumstantial evidence which offers a reasonable probability of correctness is adequate to support the verdict, the Supreme Court concluded. On the basis of all the evidence, therefore, the judgment of the trial court in favor of the plaintiff was affirmed.—*General Benevolent Association Inc. v. Fowler, 50 So. (2d) 137 (Mississippi, 1951).*

MEDICAL MOTION PICTURES

Guard Your Heart: 16 mm., black and white, sound, showing time 29 min. Prepared by the American Heart Association. Produced in 1951 by and procurable on purchase from Bray Studios, Inc., 729 Seventh Ave., New York 19.

This motion picture tells the story of Sam Taylor, a middle-aged, hard-driving executive. One day he experiences pain in the region of his heart; later he has a nightmare in which his heart talks to him and reproaches him. He is persuaded by his wife to see their family doctor, who cautions him to change his pace and, before making his examination, gives him a lecture about the heart. During this lecture, animated sequences are interspersed with live photography to illustrate the power and endurance of the heart, the way in which it performs its task of circulating the blood, and what takes place in arteriosclerosis and coronary thrombosis. There is also a brief discussion of other heart diseases. The concluding section shows Sam a changed man. He is relieved to learn that nothing is seriously wrong with his heart and that his symptoms are warning signals that he has been going too fast.

This film motivates the individual to live with his heart instead of fighting it, and it also teaches some physiology. However, the physiology, which is explained during the doctor's lecture, would be more meaningful if there were less narration and more visual illustrations. This sequence contains enough material for a film in itself. The suggestion of the producer that a discussion leader prepare his audience for the showing of the film and be ready to answer many questions after the showing is well made. The film is recommended for showing to adult lay audiences, especially persons in or approaching middle age. The photography and sound are good.

Some Aspects of Berylliosis. H. Beerman.—p. 462.

Vitamin D Intoxication.—The literature contains reports of 111 cases of hypervitaminosis-D. The syndrome consists of weakness, fatigue, and weight loss in general; nausea, vomiting, diarrhea, abdominal cramps; headache, paresthesia, and vertigo; depression, mild psychosis, and stupor; normocytic, normochromic anemia; albumin, red blood cells, casts in the urine, with progressive impairment in concentrating ability; frequency and nocturia; band keratitis; elevated serum calcium and phosphorus, with normal or slightly elevated alkaline phosphatase; progressive nitrogen retention; diffuse demineralization of the bones in advanced cases, and periarticular soft tissue calcification. Depending on the severity of intoxication, all or only a few of the above described findings will be present, as indicated in the authors' seven additional cases, which are described in some detail. Six of these patients exhibited band keratitis, a lesion commonly associated with disturbed calcium metabolism. The two most serious of the seven cases were remarkable for the demonstration of calcium-containing cysts, which were located largely in the periarticular areas and in the vicinity of the bursae. These cysts were fluctuant, did not transilluminate, and varied from 1.5 to 8 cm. in diameter. The calcium-phosphorus ratio of the sediments centrifuged from the aspirated fluid of the cysts was more than twice that present in bone. Treatment of the patients consisted of cessation of vitamin D intake, a strict low calcium diet, avoidance of undue exposure to sunlight, avoidance of alkali, maximum mobilization of the patient, and sufficient fluid intake for a daily urinary output of at least 2,000 cc. Some of the patients were given diethylstilbestrol. Vitamin D is a potentially dangerous drug and should be used only in diseases in which there is a reasonable rationale for usage. If it is used in massive doses, careful follow-up is obligatory for early detection of signs of intoxication.

Ketone Bodies in Etiology of Diabetic Coma.—There is still no general agreement as to the specific cause of coma that results from uncontrolled diabetes mellitus. Almost all authors agree that all three of the ketone bodies can have toxic effects if given in large enough doses, and some observers have demonstrated specific effects on the respiratory and other brain centers. Of the three ketone bodies, acetoacetic acid is most toxic, beta-hydroxybutyric acid is less toxic and is in equilibrium with acetoacetic acid, and acetone is a decomposition product with low toxicity. Whether they are toxic in the concentration in which they appear in the blood of patients with diabetic acidosis is unknown. The length of time they are present may be an important factor. A blood ketone level in animals of 100 mg. per 100 cc. may have no effects over a few hours but might be highly toxic if it were maintained for a week. The fact that ketosis is an absolutely constant finding in diabetic acidosis points to a strong relationship between the two. If the ketone bodies are the dominant factor in the production of coma, then some reasonable correlation should exist between the blood ketone level and the clinical state. The author's experiments showed that hyperketonemia can be produced in rabbits in the range observed in diabetic acidosis in man and maintained for several hours without apparent toxic effect. On the other hand, hypertonic saline solution of about three times the tonicity of plasma caused the death of all the animals to whom it was given. In contrast to Schneider and Droller the author believes that death was the result of the hypertonicity of the solution infused and not of the specific agent or quantity of the agent infused. In 25 cases of diabetic acidosis selected from the literature and from the author's practice, there was poor correlation of the blood ketone level with the clinical condition during therapy. Although the general trend of the ketone level was back toward normal limits this may have coincided with, rather than caused the improvement. Even if there were good correlation and good evidence of ketone toxicity, the fact that a substance can be toxic does not necessarily mean that it causes a particular clinical syndrome. It is highly unlikely that the ketone bodies are the primary cause of the clinical picture of coma. It seems more reasonable that they indicate metabolic disturbances without being toxic, just as the blood urea is a nontoxic indicator of uremia.

Intraocular Biopsy. C. A. Veasey Jr.—p. 432.

Local and Systemic Cortisone in Ocular Disease.—Leopold and his associates analyze the effect of cortisone therapy on various forms of ocular disease. The drug was administered in suspension subconjunctivally and retrobulbarly. One or both of these methods were used in 142 eyes. Systemic therapy was subsequently tried in 10 of the cases in which local therapy failed.

The Association library lends periodicals to members of the Association and to individual subscribers in Continental United States and Canada for a period of five days. Three journals may be borrowed at a time. Periodicals are available from 1940 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied with stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

Cases of allergic conjunctivitis, vernal conjunctivitis, corneal ulceration, dendritic keratitis, chemical keratitis, nonsyphilitic atypical interstitial keratitis, marginal ulcers, superficial keratitis, anterior uveitis, and sclerosing keratitis improved with local administration of cortisone. Therapy did not result in complete cure in all the cases. Relapses were frequent. The results of subconjunctival cortisone in posterior uveitis were unsatisfactory. In two cases of posterior uveitis treated by retrobulbar injection there was no significant improvement. No improvement was obtained in cases of ocular pemphigus, erythema multiforme, corneal dystrophy, congenital syphilitic interstitial keratitis, uveitis due to Boeck's sarcoid, Vogt-Koyanagi syndrome, and Harada's disease. No improvement was noted in cases of juvenile and senile macular degeneration following local or systemic cortisone therapy. Retrobulbar administration of cortisone was unsuccessful in macular degeneration and was of questionable value in posterior uveitis and retrobulbar neuritis. In 25 patients cortisone eye drops were used alone, in association with, or following subconjunctival injections of cortisone. These cases included patients with anterior uveitis, scleritis with keratitis, deep keratitis, anterior uveitis following surgery, and one patient with atypical interstitial keratitis. These patients improved following treatment with cortisone subconjunctivally, then relapsed and improved again when cortisone suspensions in drops were started. Topical cortisone used alone was helpful in allergic conjunctivitis, vernal conjunctivitis, and superficial punctate keratitis. In no case in which subconjunctival injections were unsuccessful were subsequent topical cortisone drops beneficial. Systemic administration of cortisone was more successful than subconjunctival cortisone in the treatment of posterior uveitis and of diseases of the anterior segment. Some patients improved only while cortisone was being administered and another group improved only for a while with cortisone therapy but failed to benefit from repeated and continued therapy. There is no method at present by which the permanency of cortisone therapy can be predicted. It is apparently not helpful in degenerative conditions such as dystrophy and macular degeneration. Its chief benefit seems to be in cases with active inflammatory processes.

Allergic Granulomatosis and Vascular Disease.—A clinical syndrome of severe asthma, fever, and hypereosinophilia, together with symptoms of vascular embarrassment in various organ systems, is described, and observations on 13 cases are reported. The basic anatomic changes in these cases consisted of widespread vascular lesions of the type seen in periarteritis nodosa and of characteristic tissue alteration in the vessel wall and in the extravascular collagen system. The tissue alteration found in these cases consisted of necrosis of eosinophilic exudate, severe "fibrinoid" collagen change, and granulomatous proliferation of epithelioid and giant cells. This is considered a histopathological entity and is designated as allergic granuloma. The granulomatous lesions, both within vessel walls and in connective tissue throughout the body, suggest that this syndrome constitutes an entity apart from classic periarteritis nodosa. This assumption was corroborated by review of 15 cases of periarteritis nodosa without asthma, none of which revealed extravascular granulomas or granulomatous vascular changes. Cutaneous and subcutaneous nodules showing the typical connective tissue alteration are frequent in this syndrome. These are of value for diagnosis by biopsy. Granulomatous lymphadenitis is probably also of diagnostic significance. It is suggested that other allergic syndromes (Loeffler, Zuelzer, Šikl) may represent the more benign forms of allergic granulomatosis, while angiitis is its most malignant manifestation.

Bronchi in Pulmonary Tuberculosis.—The morphological forms, incidence, and pathogenesis of bronchial tuberculosis are discussed. A relatively high incidence of endobronchial tuberculosis has been found on bronchoscopic examination of patients hospitalized for pulmonary tuberculosis. Bronchial tuberculosis appears to be more frequent in females and is generally considered to be secondary to parenchymal disease. The authors believe that the initial bronchial disease probably arises by implantation from a parenchymal lesion or from extension of adjacent disease and then spreads along the submucosa. Pronounced tuberculous bronchitis unassociated with an evident parenchymal lesion may occur. Pulmonary tuberculosis often appears as nodular "tubers" connected to both proximal and distal bronchial "roots." The proximal or larger bronchi are frequently stenosed, while the distal or smaller bronchi are occasionally dilated but are oftener destroyed by tuberculous disease. Atelectasis and varying degrees of fibrosis, plasma exudation, and alveolar macrophage accumulation and scattered tubercles accompany this peripheral bronchial disease. Pyogenic, nontuberculous responses are unusual, and nontuberculous bronchopneumonia is rarely found. Lesions of the smaller bronchi are often more numerous and severer than those of the larger bronchi. Tuberculosis of the large bronchi occurs most frequently in association with cavitation and sputum containing tubercle bacilli but occasionally may occur without detectable parenchymal lesions. Proximal bronchial disease may be important in the closure of cavities or in the production of a "blocked" cavity, in the "ballooning" of cavities, or in the production of emphysema. The presence of such bronchial lesions may account for the failure of some diseased lobes to collapse with thoracoplasty.

Neomycin in Tuberculosis.—Five patients with tuberculosis due to streptomycin-resistant tubercle bacilli and one with far advanced tuberculosis of the lungs and carcinomatosis were treated with 0.25 to 1.0 gm. of neomycin containing 200 Waksman units per milligram every 12 hr. for 29 to 52 days. The most important toxic reaction was the development of deafness in four of the six patients during the fourth to sixth week of treatment. This progressed to almost complete deafness although treatment with neomycin was discontinued immediately. All six patients showed signs of renal damage during neomycin therapy; however, the renal function rapidly returned to normal when administration of the drug was stopped. Three of the six patients reported a decrease in cough and expectoration during the period of neomycin treatment. In one instance, the patient's cough cleared completely and she ceased to expectorate. Roentgenographic evidence of improvement was established in only one of these three. Tubercle bacilli recovered at postmortem examination from one of the kidneys of a patient who died after 41 days of treatment were found to be resistant to neomycin in a concentration of 1,024 units per cubic centimeter of culture medium. Tubercle bacilli recovered from the lungs, spleen, liver, and omentum, however, were found to be sensitive to 1.0 unit or less of neomycin per cubic centimeter of culture medium. Neomycin in sufficiently large doses is a potent antibacterial agent against the tubercle bacilli in experimental tuberculosis in animals. In the present study, suggestive indications of antimicrobial effect were observed in the one patient who received the largest daily dose (2.0 gm.) of the drug. The other five patients, who received a smaller dose of neomycin, had only symptomatic benefit and the postmortem examination in one case revealed no evidence of suppression of the disease. The toxic reactions to neomycin render the particular preparation of the drug studied of little or no clinical value in tuberculosis, even if the smaller doses used in this study were therapeutically effective. Whether the toxic reactions were due to neomycin itself or to something else in the material is not known. The recovery of neomycin-resistant tubercle bacilli from one of the kidneys of a patient after 41 days of treatment suggests that tubercle bacilli become resistant to neomycin as readily as to streptomycin.

Tuberculostatic Activity of Terramycin.—The sensitivities, in vitro, of a number of human strains of tubercle bacilli to terramycin and its salts were determined. Four to 16 γ of pure terramycin per milliliter of medium were sufficient to inhibit growth of these strains. Terramycin was found to be no more active than aureomycin against tubercle bacilli, in vitro. Terramycin is active against both streptomycin-sensitive and streptomycin-resistant strains. This suggested that terramycin might be especially effective when used in combination with streptomycin or other antituberculous agents. In *vitro studies* have shown that one-fifth to one-tenth of the amount of terramycin required for inhibition of growth significantly decreases the concentrations of streptomycin, viomycin, and aureomycin necessary for inhibition of growth. The effect on the concentration of chloramphenicol or penicillin necessary for inhibition of growth was less pronounced. No change in the amount of neomycin required for inhibition of growth was observed. Terramycin exerts a bactericidal effect only if high concentrations are used. Organisms resistant to its action emerge from otherwise sensitive strains at an exceedingly slow rate. None of the five strains of Mycobacterium tuberculosis tested showed any significant increase in resistance during 12 transfers in liquid medium that contained subinhibitory concentrations of terramycin. Studies on the chemotherapeutic action of terramycin against tuberculous infections were carried out in mice infected intracerebrally. In a rapidly progressing infection, in which the average survival time of the untreated control animals was 24 days, a dosage equivalent to 8.6 mg. of terramycin per 20-gm. mouse was sufficient to increase the average survival time to 120 days. Lower doses of the sodium salt of terramycin, equivalent to 1.1 to 2.2 mg. per day, were sufficient to cause an approximately three-fold to four-fold increase in survival time. Terramycin, in both its amphoteric form and its sodium salt, was effective in suppressing this infection. The activity of terramycin in vitro and in vivo against streptomycin-resistant strains of tubercle bacilli and its low toxicity suggest that this agent may be therapeutically valuable.

Lesions of Cervical Stumps.—Collins and his associates analyzed a series of 226 patients who, after supravaginal hysterectomy, had symptoms arising in the cervical stump warranting its surgical excision. They did not include in this analysis patients in whom symptoms were relieved by simple cauterization. Almost one-third of the patients still had the same complaint for which the original pelvic operation had been performed. Removal of the cervix produced relief. Multiplicity of symptoms was the rule. Nearly half of 226 patients had pelvic pain; 105 had leukorrhea; 84 had bloody discharge; 72 had dyspareunia; 56 had backache; 60 had urinary discomfort, and 34 had bearing down pain. In the absence of fixed pelvic masses the ability to reproduce exactly a patient's symptoms by gentle motion of the cervix means that the cervix is the etiological factor. Production of local pain is possible in any woman if the examination is very vigorous. Cervical erosion and chronic cervicitis were present in nearly 90% of the patients. Other lesions were stenosis or stricture, empyema, epidermoid carcinoma, endometriosis, fibroids, polyps, squamous metaplasia, endocervical hyperplasia, ulceration, mucocele, and leukoplakia. There were 10 patients (4.4%) with carcinoma. When hysterectomy is indicated, total abdominal hysterectomy or vaginal hysterectomy are the procedures of choice. Supravaginal hysterectomy is *rarely indicated*. If it has been performed, the cervix should be inspected at frequent intervals. If the cervix is diseased or symptomatic, cauterization or vaginal excision of the cervix is advisable.

Gastric Contents in Lungs During Anesthesia and Surgery.—Aspiration of gastric contents is a serious, often fatal accident during general anesthesia. Vomiting is only part of the problem, for silent aspiration of gastric contents by the deeply anesthetized patient is also common. The authors made studies on 300 surgical patients to determine the causes and frequency of these accidents. Four cubic centimeters of a 25% aqueous solution of Evans blue dye (T-1824) were introduced into the stomach preoperatively. As soon as the operation was over, the mouth, pharynx, larynx, trachea, and main bronchi were inspected by direct vision through laryngoscope and bronchoscope. Regurgitation (as indicated by dyed stomach contents in the pharynx) occurred in 79 of the 300 patients; 24 of these showed frank vomiting. Forty-nine patients aspirated gastric contents into the lungs. Regurgitation occurs much oftener when the patient is in the Trendelenburg or the lateral position than when he is in the horizontal supine position or the lithotomy position. Gastric tubes are protective, presumably by keeping the stomach contents low in volume. When the stomach is not empty, pressure on it by the surgeon during work in the upper abdomen may possibly force gastric contents into the pharynx. The volume of the aspirated material may produce fatal obstruction, but the irritant and infectious action of the aspirated material also may be serious. The stomach should be emptied by induced vomiting when emergency surgery must be undertaken. Even 15 or 20 hours after the onset of an emotional crisis or a painful injury the stomach may still hold whatever contents it had at the beginning of that time.

Aureomycin in Surgical Infections.—Of 263 surgical patients treated with aureomycin some received it exclusively from the beginning, others were given it after they had proved refractory to other antibiotics, and still others received it in combination with other chemotherapeutic agents. Aureomycin effectively suppressed the normal intestinal flora and gave excellent results in 67 cases in which gastrointestinal surgery was done. Alone, or in combination with penicillin, aureomycin was effective in the therapy of diffuse peritonitis due to intestinal bacteria. It produced improvement in all and cure in most patients with urinary infections, due chiefly to gram-negative bacilli, providing appropriate surgical treatment was given when indicated. It seemed to control biliary tract infections, and it served as a valuable adjunct to surgery in infections of the extremities with peripheral vascular disease. Postoperative wound infections and miscellaneous infections, including acute infections of the soft tissues, acute osteomyelitis, acute parotitis, Vincent's angina, acute hepatitis, and herpes zoster, responded to aureomycin. This drug was frequently effective in infections that had failed to respond to other antibiotics, and it was equally effective in mixed and in unimicrobial infections. The drug was administered orally, intramuscularly, or intravenously. Recently the intramuscular route has been discontinued. The toxicity of parenterally administered aureomycin is almost negligible, but some lots of the drug for oral administration continue to cause nausea, anorexia, or diarrhea. In some patients, severe proctitis or colitis developed during oral aureomycin therapy. The accompanying diarrhea was so severe that the patients' fluid and electrolyte balance became seriously impaired. In several instances the bowel was edematous, hyperirritable, and in almost continuous spasm. Stomatitis and esophagitis with dysphagia, substernal pain, and "burning" lasted several weeks in some cases.

*Artificial Pneumothorax Evaluation Based on Complications. J. L. Porrata-Armstrong.—p. 151.

Artificial Pneumothorax.—According to Porrata-Armstrong the use of therapeutic pneumothorax has become limited in the past few years. It is still, however, the treatment of choice in unilateral pulmonary tuberculosis with or without a small cavity of recent appearance that has not responded adequately to bedrest, either alone or combined with specific therapy. The amount of exudation and caseation in the surrounding tissues and the bronchial lesions, as shown by bronchoscopy, should be minimal. Careful management of artificial pneumothorax includes the following measures: 1. Proper spacing of refills, so that optional collapse is maintained without too much fluctuation. Too much collapse is dangerous; too little is ineffective. 2. Fluoroscopy prior to each refill. 3. Determination by manometric reading that the pneumothorax needle is in the pleural space. 4. Avoidance of positive pressures. 5. Avoidance of puncturing the underlying lung. 6. Adequate bacteriological studies, including cultures of gastric washings and of sputum. 7. Proper coordination with antituberculous therapy. 8. Abandonment of the pneumothorax at the proper time, namely, when there is persistence of a cavity after an adequate trial (two to three months), increase in size of cavity during collapse, development of large and intractable pleural effusion, and rapid obliteration of the pleural space by adhesive pleuritis.

Polyarteritis Nodosa.—The clinical and pathological findings were studied in 14 men and three women between the ages of 30 and 72 with polyarteritis nodosa. It was observed that this disease occurs most commonly among men between 40 and 50. Caucasians predominated over Negroes. The authors found no close etiological relationship between allergy and polyarteritis nodosa. Eosinophilia, which was considered by some to be one of the most significant laboratory findings, occurred in only one of the 17 patients, and this patient had had bronchial asthma for many years. The authors believe that polyarteritis nodosa and hypersensitivity angiitis are two different conditions and that it is the latter that is characterized by allergic manifestations, including eosinophilia. Pain was the commonest symptom and was observed in 11 patients. Shortness of breath, due to either heart failure or nonspecific pulmonary complications, was observed as a late symptom in eight patients. Tachycardia, fever, and edema were the outstanding signs. In all 17 cases there was no consistent correlation between the clinical findings referable to the cardiovascular system and specific types of pathological changes in the organs of this system. Hypertension is one of the commonest signs of polyarteritis nodosa and was observed in 13 of the authors' patients. It may develop very late, however, and failure to diagnose polyarteritis nodosa because of the absence of hypertension will lead to error, as may the absence of eosinophilia and subcutaneous nodules. The changes in the electrocardiogram were not specific and were due to myocardial ischemia and scarring. There also was no consistent correlation between the clinical evidence of renal damage and specific types of pathological changes in the kidneys. The frequent association of glomerulonephritis and polyarteritis nodosa reported in the literature previously was confirmed. In all 13 patients with hypertension pathological renal lesions were demonstrated. Involvement of the gastrointestinal system was common, and occurred in 10 of the 17 patients, with abdominal pain, nausea, and vomiting as the most frequent symptoms. The lesions were distributed throughout the viscera. The most commonly involved organ in the abdomen was the liver. Splenomegaly was observed in only three patients. The central nervous system was examined microscopically in nine cases. Four of these showed characteristic changes in the cerebral vessels. According to this study, pulmonary involvement in polyarteritis nodosa is rare, as it was observed in only one case.

Disseminated Lupus Erythematosus.—Eighteen cases of acute and subacute disseminated lupus erythematosus were verified by postmortem study in a series of 19,242 autopsies. The disease was observed to be commoner among women between the ages of 22 and 33. Pain in the joints was the commonest symptom and was observed in 13 of the 18 cases. The typical butterfly rash occurred in 11 cases. Nonspecific skin lesions were observed in four other cases. Shortness of breath was the commonest complaint and occurred in 16 cases. In 14 of these there was an alteration of the connective tissue and muscle fibers in the myocardium, but there was no constant correlation between clinical findings and specific pathological lesions. Neither murmurs heard over the precordium nor QRS and T wave changes seen in the electrocardiogram were pathognomonic for the disease. Of seven patients with apical systolic murmurs only two had nonbacterial verrucous endocarditis of the mitral valve leaflets; conversely, of six patients with nonbacterial verrucous endocarditis only two had an apical systolic murmur. Albuminuria was the commonest laboratory observation, being observed in 14 of 17 patients in whom urinalysis was performed. The often observed wire-loop changes of the glomeruli may cause albuminuria, leukocyturia, cylinduria, high nonprotein nitrogen of the blood, and hypertension collectively, or one of these signs separately, or there may be no clinical findings. In the absence of the typical butterfly rash in seven cases, the observations most constant and suggestive of the disease were (1) polyarthralgia of undetermined origin, (2) fever and tachycardia of unknown cause, (3) albuminuria alone or together with hematuria, and cylindruria, (4) leukopenia, and (5) signs and symptoms of serosal inflammation. The clinical diagnosis is confirmed by biopsy of the skin lesion, the observation of anemia and leukopenia, a high globulin content in the serum (above 2.5 gm. per 100 cc.), and the detection of typical L. E. cells in the peripheral blood or in the bone marrow.

Cortisone and Acute Streptococcic Infections.—The authors studied 174 patients with acute streptococcic tonsillitis and pharyngitis to determine the effect of cortisone on the disease and on the subsequent incidence of rheumatic fever. The patients were divided into treated and control groups. Two treatment schedules were employed. Seventeen patients received a total of 500 mg. of cortisone acetate intramuscularly in 50 mg. doses. Seventy patients were given a total of 600 mg. in 100 mg. doses. Control patients received 0.85% sodium chloride injections. No antipyretics or other medications were given, except codeine for relief of severe headache. Patients were examined daily through the sixth day of illness by one member of the staff who had no knowledge of the treatment being administered. Cortisone therapy had no effect on symptoms or physical signs of this infection. Patients who received cortisone had fever for a longer period than the control patients. Suppurative complications developed in one of the treated patients and in three of the control subjects. Rheumatic fever was diagnosed in two treated and five control subjects. The increase in the antistreptolysin titer was somewhat less in the serums of the treated group than in the control patients one week after the onset of infection, but at two, three, and four weeks the formation of antibody was slightly greater in treated than in control patients.

Encephalopathy Following Barbiturate Intoxication.—Barbiturate poisoning is generally followed by either complete recovery without neurologic sequelae or death within the first 48 hours. The case reported here is of special interest because the patient lived in a state of semistupor for nearly five months after the ingestion of about 70 grains (4.7 gm.) of phenobarbital and 24 sedormid® (allyl-isopropyl-acetyl-carbamide) sedative tablets without fully recovering social awareness. Massive cerebral infarction and acute bronchopneumonia were regarded as the cause of death. Destructive parenchymatous lesions and progressive proliferative changes in the glia were found. The predominant changes were in the form of laminar cortical degeneration associated with less prominent basal ganglion damage. These changes are not specific, as similar lesions have occurred as the result of poisoning with carbon monoxide and other noxious agents. It is suggested that a direct chemical action of the poison on the nerve cells may be as important a factor as is anoxia in the production of the cerebral changes.

Treatment of Epilepsy by Cortical Excision.—Primary therapy for a patient suffering from convulsive seizures consists of anticonvulsive medication, psychotherapy, and social and occupational rehabilitation. Operative intervention should be considered when medical management has failed to control the seizures. If there is evidence of a progressive lesion of the brain, such as tumor, abscess, or hematoma, appropriate surgical measures are imperative. Thus only 20 to 25% of patients with focal epilepsy become candidates for surgical intervention. The focal nature of an epilepsy may be suggested by the clinical history, the electroencephalogram, pneumoencephalogram, and angiogram but must be established by critical examination of the entire clinical picture together with the results of the various diagnostic tests. If a discrepancy between these various examinations becomes apparent, it should be considered that two foci exist or that the condition is idiopathic rather than focal epilepsy. Three cases of focal epilepsy, in boys 15, 12, and 11, respectively, are reported on, illustrating the various types of cortical resections for this condition. Subpial resection was adequate and should produce minimal scarring in the first case. The epileptogenic zone involved a large area at the occipital pole in the second case, requiring partial occipital lobectomy. In the third patient, with infantile hemiplegia, hemispherectomy was necessary to eliminate the abnormal, scarred tissue. The end results of surgical treatment cannot be assessed accurately until the patients have been followed for at least five years, but the physical and mental improvement that followed the surgical resection of epileptogenic foci in isolated cases offers much promise to a group of patients with focal epilepsy otherwise considered incurable.

Illness in First Trimester of Pregnancy.—Of 1,228 mothers who gave birth to 1,237 infants in 1948 at St. Mary's Hospital in Rochester, Minn., 148 mothers were ill at some time in the first trimester of pregnancy. These ill mothers subsequently gave birth to 149 children, eight of whom (5.4%) had congenital anomalies. The 1,080 mothers who were not ill in the first trimester of pregnancy gave birth to 1,088 infants of whom 57 (5.2%) had congenital anomalies. Thus, there was no significant difference between the incidence of congenital anomalies following maternal illness in the first trimester of pregnancy and that following uneventful pregnancy. Furthermore, illness in the mother in the first trimester of pregnancy apparently was not significant in the incidence of full-term pregnancy, prematurity, or stillbirth.

*Dental Hypoplasias in Relation to Congenital Syphilis. S. B. Beecher, H. N. McIntosh and E. J. McCart.—p. 70.

Dental Hypoplasias in Congenital Syphilis.—The authors made a survey in 18 public schools for Negroes in Missouri to determine the incidence of congenital syphilis in children with dental hypoplasias suggestive of syphilis. The syphilitic hypoplasias that affect the permanent incisors and six year molars are known as Hutchinson's incisors, mulberry molars, and the bud molar of Pfluger. The public health dentist examined 1,639 children. Each child who was a suspect and the child's mother were called so that the family's medical history and serologic tests for syphilis could be taken. The family of each seropositive child was examined by the medical officer. Of 54 suspects reported by the dentist, 50 were serologically tested for syphilis and 16 were found to be infected with congenital syphilis. The results of this project indicate that the cooperation of dentists would be of practical value in case finding. The venereal disease investigator could expect to find 25% of the suspected patients infected with congenital syphilis.

Licorice in Addison's Disease.—Borst recently demonstrated that glycyrrhiza (licorice) extract causes sodium retention and potassium loss leading to an increase in extracellular fluid, plasma volume, venous pressure, and pulse pressure. He concluded that glycyrrhiza contains a substance with desoxycorticosterone-like action. Groen and co-workers then administered 15 gm. of glycyrrhiza extract per day to a patient with Addison's disease previously controlled with desoxycorticosterone acetate. Mineral equilibrium was maintained as long as the glycyrrhiza therapy was continued. Withdrawal of the extract was followed by reappearance of the clinical, biochemical, and hemodynamic disturbances. A second course, of 30 gm. daily, again produced clinical and laboratory remission. In another patient with Addison's disease a crude extract of one of the main ingredients of the extract, ammonium glycyrrhizinate (3.3 gm. daily orally), maintained sodium, potassium, and chloride equilibrium. Glycyrrhizonic acid is a component of glucuronic acid and glycyrrhetinic acid. The latter is a polyterpene with a structural formula exhibiting a striking resemblance to the cyclopentenophenanthrene steroids, to which group desoxycorticosterone belongs.

Tantalum Mesh in Eventration of Diaphragm.—Monahan reports a case of eventration of the right leaf of the diaphragm associated with massive hemorrhage from a duodenal ulcer. The patient was explored thoracically, and the diaphragm was pleated and reinforced with tantalum mesh. Subsequent bleeding necessitated an emergency gastric resection. Roentgenograms taken 15 months after operation showed the repair to be intact and the diaphragm remaining in its new position. It may be concluded that tantalum mesh can be placed next to the lung without harmful effects and with no more effusion than one would expect to occur after an exploratory thoracotomy.

Vitamin A Poisoning.—The occurrence of hypervitaminosis A is reported in two children, a boy 2½ years and a girl 17 months. A survey of the literature revealed records of only 14 cases, all in infants and children, with symptoms of overdosage with vitamin A. The authors' first patient was admitted to the hospital because of irritability, failure to walk, and roentgenologic evidence of cortical thickening of bone suggesting scurvy or leukemia. He also had lesions around the mouth resembling those of vitamin B complex deficiency. A survey of the child's vitamin status in general was undertaken and an elevated fasting vitamin A level of 837 γ per 100 cc. was found. History revealed excessive vitamin A intake. The fasting vitamin A level two days later was 695 γ per 100 cc., of which 67.3% was in the alcoholic form. This elevated level of alcoholic vitamin A, probably denoting large stores of vitamin A in the liver, appears to be a better index of hypervitaminosis A than the total vitamin A level. In addition, evidence has been presented that the toxic factor in hypervitaminosis A is the persistently elevated plasma vitamin A level. The authors' second patient had a history of excess vitamin A intake and the characteristic clinical and roentgenograpihc findings. The symptoms disappeared after cessation of high vitamin A intake. It is suggested that excess intake of vitamin A causes saturation of the tissues, which leads to pathological changes involving the epiphyseal and appositional bone growth, which consist of increased density of the epiphyseal lines and cortical thickening. Cortical thickening apparently causes the tenderness of the extremities that was seen clinically. It cannot be emphasized too strongly that excess vitamin intake may be as dangerous as a deficient intake.

Gastrointestinal Lesions in Bulbar Poliomyelitis.—Five children, between the ages of 3 and 11 with severe bulbar poliomyelitis complicated by gastrointestinal perforation and/or hemorrhage are reported on. Four of the patients died. The gastrointestinal lesions were associated with respiratory center involvement in all the patients. The electrophrenic respirator was instrumental in maintaining the respiration of the surviving patient. Massive blood transfusions given to this patient prevented shock from intestinal hemorrhage. The gastrointestinal complications of bulbar poliomyelitis appear to be more frequent than previously realized. A relationship between midbrain damage and gastrointestinal lesions, as emphasized by Cushing, occurring during the course of acute bulbar poliomyelitis, is postulated. Routine guaiac tests should be performed on the stools of all patients with acute bulbar poliomyelitis, so that the presence of gastrointestinal bleeding may be recognized as early as possible. Therapy for these desperately ill patients should include blood transfusions since, as demonstrated by the authors' surviving patient, this condition can be controlled.

*Hazards of Shoe-Fitting Fluoroscopes. W. W. Van Allen.—p. 375.

Hazards of Shoe-Fitting Fluoroscopes.—Shoe-fitting fluoroscopes present two distinct radiation problems: (1) the direct radiation received by the customer, and (2) the radiation received by the shoe store personnel. In the first case, radiation exposure is brief but relatively intense. Conversely, clerks and other personnel in the store are subject principally to secondary radiation in varying quantities, depending on their position and habits during examinations. The author of this report examined several shoe-fitting fluoroscopes and measured their radiation characteristics. Considering the very short target-foot distance in these machines, amounting to approximately 6 in. (15.24 cm.), high dosage rates are to be expected. The secondary radiation, immediately behind the customer, may be as much as 50 to 100 milliroentgens per minute. Since the maximum permissible radiation dosage rate is defined as 300 milliroentgens per week, it is clear that this safety limit could easily be exceeded by a clerk who regularly stands in this region. Measures for reducing the radiation hazards inherent in shoe-fitting fluoroscopes are discussed. It is important that shoe store operators be educated about the x-ray equipment that they use in their business. Unfortunately, there is no way to prevent customers from going from one store to another and receiving one or more exposures in each. The city of New York requires the display of warning cards advising against more than three exposures a day, or 12 per year. It should be noted, however, that this limit of three exposures per day is predicated on a maximum radiation dosage of 2 r, which is much lower than any of the dosages actually encountered in a survey.

Postoperative Study of Vagotomy.—From a follow-up study of 130 patients on whom vagotomy was performed for peptic ulcer, Walters and Belding reached the following conclusions: 1. Vagotomy is not indicated in the treatment of gastric ulceration, the procedure of choice being gastric resection. 2. Vagotomy alone is rarely indicated in the treatment of duodenal ulceration, and it adds little to such simultaneously performed procedures as gastric resection and gastroenterostomy in the prevention of recurrent ulceration. In addition it has increased the postoperative morbidity and mortality. 3. Vagotomy is an extremely valuable operation in cases of gastrojejunal ulceration after adequate gastric resection. It is of further value combined with a second resection of the stomach for gastrojejunal ulcer, when inadequate resection has been done. 4. There is probably a place for vagotomy in the treatment of small gastrojejunal ulcers or of hemorrhagic gastrojejunitis after gastroenterostomy. In most cases, however, gastric resection is preferred. The wide variety of opinions in regard to the efficacy of the operation is probably due to the differences in the results obtained from clinical follow-up and from questionnaires, and to the failure of some observers to make objective studies one and one-half to two years postoperatively. The authors also observed that following vagotomy alone disturbances of motility persisted in 26.4% of cases studied one to four years after operation and acidity returned to preoperative levels in 23.7% of cases. The results of the insulin test correlated well with clinical results in 80% of all cases but in only 23.1% of the cases with poor clinical results, which indicates that this test is a poor prognostic index of recurrence of ulcer.

Postoperative Use of Adrenal Cortical Extract.—During periods of extreme heat, postoperative patients frequently have a severe febrile reaction. The two noxious agents, heat and the trauma of the surgical procedure, undoubtedly act as stimuli on the adrenal cortex, and certain changes in these patients appear to be related to altered adrenal activity. It was thought that the administration of an adrenal cortical preparation containing larger amounts of the 11-oxyadrenal steroids might be of value in ameliorating the condition. Women were selected for the study, since 17-ketosteroid production in them is probably entirely of adrenal origin. Ten of the 20 unselected women, who were undergoing major pelvic surgery for gynecologic disorders, received no adrenal cortical therapy and served as controls. Treatment with adrenal cortical extract was begun 12 hours before the operation, when 20 units were given intramuscularly. An additional 40 units were given immediately before and 20 units six to eight hours after the operation. During the first two postoperative days, 40 units were administered daily in two injections of 20 units each. Thereafter, for two days, the total daily dose was 20 units. The total dose was 200 units. The benefit of these rather small doses was evidenced by the clinical course. In most instances, the patients given the medication were subjected to rather more extensive surgery, and they stood the procedure well. Comparison with untreated patients subjected to at least equal surgical trauma revealed that the postoperative course of the treated patients was more satisfactory than that of the untreated group. The sense of well-being was greatly augmented, and recovery was attained without the occurrence of urinary retention, inanition, and other possible complications.

Technique of Vagotomy and Gastroenterostomy in Duodenal Ulcer.—Crile discusses the disadvantages when either vagotomy or gastroenterostomy are used alone and then stresses the advantages of the combined use of these two methods for duodenal ulcer. Most of the so-called side effects of vagotomy are the result of gastric retention and can be avoided by a combination of vagotomy with a well placed gastroenterostomy. The gastroenterostomy should be placed at the most dependent part of the denervated stomach, so as to allow drainage by gravity. It should be posterior and antiperistaltic, parallel to the greater curvature, and as close to it as possible. The vagotomy must be complete enough to protect the vulnerable gastroenterostomy from recurrent ulceration. A technique of vagotomy is described in which the nerves are put on tension and are located by palpation.

Transposition of Colon Segment as Gastric Reservoir.—Lee describes an experimental procedure for transposition of the ascending colon and terminal ileum as an artificial gastric reservoir. The transposition was performed on 19 animals. Of these, eight died in shock before adequate supportive measures were instituted. Of the remaining dogs, six succumbed to leaks due to the presence of ingested hair. Of the other five, two died from obstruction and three survived for 14 days or longer. Thus in no case of ascending colon transposition was death due to circulatory embarrassment as a result of rotation of the right colon and implantation of it in the position of the normal stomach. In three human patients the operation was performed with encouraging results. The patient was a man, 53, who had a large carcinoma involving the greater curvature and posterior surface of the stomach in the region of the spleen. The operation, including incision and closure, required five hours, and the patient received three units of whole blood. He was ambulatory on the second postoperative day. Although the new "stomach" had been in place only 14 days, peristaltic activity was good and the reservoir emptied well. While transposition of the ascending colon is the preferred procedure, a segment of transverse colon might be used in selected cases. The operation, though well tolerated in this case, is of such magnitude that it should not be undertaken as a palliative procedure. Its use should be reserved for those patients in whom there is definite hope of cure. It is hoped that further favorable experience with this operation will serve to remove one of the major objections to total gastrectomy and to increase the salvage rate in gastric carcinoma.

Carotid Body Tumors.—Carotid body tumors are relatively uncommon. Their clinical recognition is difficult, as is the selection of a proper method of treatment. They occasionally surround and fuse with the carotid arteries in such a way that the tumor can be removed only by division of these vessels. These tumors are, for the most part, benign, slowly growing, and relatively asymptomatic. There was no proved instance of malignancy in the true carotid body tumors in the 23 patients observed. There were four deaths in the group, a mortality rate of 17.4%. These occurred in the group of 20 patients in whom the carotid body tumor had been excised, giving a 20% mortality rate for resection. In six patients in whom excision of the tumor was accompanied by immediate ligation of the common, internal, and external carotid arteries the mortality rate was 50%. Since the common carotid artery alone was ligated in two additional patients as a preliminary step to excision of one carotid body tumor and one glomus jugularis respectively, a total of eight patients had ligation of the common carotid artery, with three deaths (37.5% mortality). Because of this forbiddingly high mortality rate, it is concluded that tumors of the carotid body should not be excised when this would require the ligation of the internal, external, and common carotid arteries, unless the tumors are shown by biopsy to be malignant or are enlarging intrapharyngeally so as to interfere with swallowing or cause pain.

Posttransfusion Viral Hepatitis.—Ginzburg and co-workers report 15 cases of homologous serum jaundice following the use of whole blood and review four of these cases. Failure to consider homologous serum jaundice as a cause of delayed postoperative jaundice in patients who have been given transfusions may lead to serious diagnostic and prognostic errors and to hazardous, unnecessary operative procedures. The disease itself may be very serious. In this series the symptoms of onset were relatively mild, consisting of loss of appetite, nausea, and occasionally mild vomiting and diarrhea. Jaundice was sometimes observed before the development of other symptoms. The jaundice lasted between one and three months, reaching its height at about four to six weeks. Once the jaundice subsided there was no recurrence. In five instances in which tests were performed shortly after the subsidence of jaundice, persistence of residual hepatitis was suggested by cephalin flocculation and thymol turbidity tests, which still gave positive results, but to a lesser degree than at the height of the icterus. In three instances in which these tests were repeated four months later, results had become negative. In about half the cases, moderate, smooth, nontender, palpable hepatic enlargement developed and then receded as the patient improved. Jaundice due to either cicatrization following trauma or metastatic neoplasm is almost invariably of an obstructive type, whereas that occurring in homologous serum jaundice is nonobstructive. The authors discuss differentiation of the two types. There is evidence that homologous serum jaundice is caused by a virus in the blood of the donor that is introduced directly into the bloodstream of the recipient. The presence of an undetectable carrier state constitutes a serious danger in the use of "unknown" donors. The authors conclude that blood for transfusion purposes should be supplied from donors whose background are known and whose histories are reliable. Until a laboratory test is available that can exclude carriers of the virus, the danger of transmission of this disease exists and may soon serve as a curb to the ever-increasing use of whole blood just as it did to the use of pooled plasma.

*Tuberculosis in Thyroid Adenoma. U. Frasson.—p. 1141.

Tuberculosis in Thyroid Adenoma.—Microscopic examination of thyroid adenomas removed from 72 patients in a municipal hospital revealed three cases of tuberculosis of the thyroid. The three patients showed no symptoms or signs of thyroid tuberculosis, and the glands appeared grossly normal, but microscopically they showed granulomas of the tuberculous type outside the colloid-containing cavities of the thyroid. These were readily differentiated from subacute parenchymatous thyroiditis. From the clinical course of the disease and the histopathological findings, the author concludes that thyroid tuberculosis may develop in a normal gland or in an adenoma. It does not, however, stimulate thyroid adenomas.

Syringe Needles and Mass Inoculation Technique.—Faulty methods of sterilization of syringes and needles in mass inoculations have been known to result in transfer of infections. Fleming and Ogilvie sought a safe substitute for the dangerous method of changing the needle between each patient. In this paper experimental evidence of the efficacy of the hot oil sterilization method of sterilizing needles is presented. Without being removed from the syringe, needles can be sterilized by immersion for 10 seconds in liquid paraffin at 130 C. or higher. If hot oil is not obtainable, immersion of the needle for 10 seconds in boiling water is effective. Oil is preferable, as the needles remain sharp for a longer time and do not rust. When multiple doses are given from one filling of the syringe there is a second problem to be considered, namely, the possibility of reflux of fluid from the body of the inoculated man into the syringe. Accidental movement of the piston of the syringe or pressure in the tissues may cause such reflux. This method is therefore dangerous, even if the needle is thoroughly sterilized. It has been shown that if only one dose is taken up into the syringe and if, after inoculation, pressure is kept up on the piston until the needle is withdrawn, there is no reflux of fluid into the syringe. This method of inoculation, combined with sterilization of the needle by 10 seconds' immersion in oil at 130 C., seems to be perfectly safe and rapid enough for mass inoculation.

*Injuries of Peripheral Nerves After Injections. K. Kolle.—p. 367.

Injuries of Peripheral Nerves After Injections.—Kolle believes that postinjection nerve injuries are not so rare as the scanty literature indicates. The first case he cites is that of a man in whom an irreparable paralysis developed in the region of the tibial and fibular nerves after a soluble quinine hydrochloride preparation had been injected into the flexor surface of the thigh. The patient had a severe pain, and it was later found that the injection had been made into the sciatic nerve. The patient was unable to work for several years. The middle portion of the flexor surface of the thigh is unsuitable for intramuscular injection, particularly in thin persons. The case of a patient in whom paralysis of the radial nerve developed illustrates that subcutaneous injections also may produce nerve injuries. Several cases are cited in which nerve lesions with impaired sensibility developed after intravenous injections. An anatomic illustration of the bend of the elbow shows that the danger of a nerve injury always exists when a medicament is injected into the vena basilica or the vena mediana cephalica and that, therefore, in this region injections should be made into the vena mediana basilica.

*Vitamin K in Treatment of Bacillary Dysentery. M. F. Krause.—p. 361

Vitamin K in Bacillary Dysentery.—Krause administered vitamin K to three series of adult patients with bacillary dysentery. In the first series of six patients the intramuscular injection of pure vitamin K had no effect on the disease. In the second series of four patients, the oral administration of 5 to 10 mg. of vitamin K with bile salts, four times daily, resulted in cure in three days. Still better results were obtained in the last series by the oral administration of vitamin K without bile salts. The drug was given in doses of 10 mg. every two hours for two days. Cure was obtained on the first day of the treatment. The patients were discharged from the hospital on the third day. The drug was well tolerated. The author concludes that (1) vitamin K kills Shigella disenteriae or (2) bacilli of the coli group lose in certain circumstances the capacity of producing vitamin K and that this loss results in decreased resistance of the host to S. dysenteriae, increased virulence of the organism, or actual transformation of bacilli of the coli group into virulent bacilli of the dysenteric and paradysenteric group.

Surgical Treatment of Otosclerosis.—Cawthorne reviews the present status of the surgical treatment of otosclerosis. His technique is based on Lempert's nov-ovalis approach, in which a window is made in the anterior part of the bony external semicircular canal and adjacent ampulla. This opening is covered by a flap derived from the skin covering the anterior wall, roof, and posterior wall of the bony external meatus, continuity with the intact tympanic membrane being preserved. The fenestration operation is most likely to be successful when the otosclerotic bone is limited to the region of the oval window. Extensive spread of otosclerotic bone, either over the surface or

---

An asterisk (*) before a title indicates that the article is abstracted. Single case reports and trials of new drugs are usually omitted.

into the cavities of the bony labyrinth, renders a patient unsuitable for the operation, therefore, clinical indications of such extensive growth should be carefully sought. These are alteration in the timbre of the voice, intolerance of amplification, disappearance of paracusis, reduction of bone conduction, and pink-tinged tympanic membrane. The operation should be done only by those specially trained for it, and, with a skilled operator, more than two-thirds of the patients can expect lasting improvement in hearing. For those who are unsuitable for or unwilling to face surgery, a good valve-amplified hearing aid usually improves the hearing. Surgery is only part of the management of the patient suffering from this form of deafness.

Sensitivity of Rectum and Anal Continence.—Goligher and Hughes describe the sensations produced by distention of the rectum and distal colon. A balloon, mounted on the end of a narrow graduated rubber tube, was inserted into the rectum and the lower part of the sigmoid colon. The balloon was inflated at various levels, and the minimum pressure required to produce sensation and the patient's description of the sensation were recorded. Distention of the bowel up to 15 cm. from the anal orifice caused a sensation of fulness in the rectum, producing the urge to pass gas or feces—a rectal type of sensation. Distention above this level produced a purely abdominal sensation, referred to the suprapubic or left iliac region and simulating a gas pain or intestinal colic—a colonic type of sensation. Interruption of the nerve supply to the rectum and colon by anesthetic block or operative division showed that the colonic type of sensation is mediated by the sympathetic system and the rectal type by the parasympathetic system. Balloon distention causing rectal sensation evoked a contraction of the external sphincter ani that appeared to be partly reflex and partly voluntary. This was never produced by colonic distention. A rectal type of sensation never develops in the terminal colon after colostomy but may develop to a small degree in stumps of colon drawn into the pelvis by sphincter-saving resections. This spurious rectal sensation is unfortunately no adequate substitute for genuine rectal sensation in the maintenance of anal continence. Hence, in the performance of sphincter-saving excisions, if a good functional result is to be insured and "sensory incontinence" avoided, it is essential to preserve undamaged not only the sphincter muscles but also at least 6 cm., and preferably 8 cm. or more, of anorectal stump with its parasympathetic nerve supply.

Hypotensive Action of Veriloid.—Veriloid is a stable extract of veratrum viride biologically standardized according to its vasodepressor effect in dogs. Its three major effects are hypotension, emesis, and bradycardia. It was administered by mouth to 10 hospitalized patients (five men and five women) with hypertension and intravenously to an 11th patient. Given by injection it rapidly reduces the blood pressure, so that it should prove of value in hypertensive encephalopathy and the convulsions of puerperal eclampsia. Given orally, its absorption is difficult to control and its effect lasts a relatively short time, with the result that uniform lowering of the blood pressure is not readily obtained; but the variations can be kept at a lower level, and symptomatic relief is usually attained. The margin between therapeutic and toxic levels, where high dosage is necessary, is small. This makes the fixed arteriosclerotic type of hypertension unsuitable for treatment. Because of vagus action, veriloid is best avoided in the presence of peptic ulceration. Its main field of usefulness is in the younger patients with severe benign or malignant hypertension and possibly in those with chronic nephritis.

Infection of "Clean" Surgical Wounds.—Prophylaxis of "clean" surgical wounds includes the care of the patient as a whole and of the tissues of the wound in particular, and many preventive procedures, including the good design and ventilation of the operating theater. A case is reported in which a wound became infected with a type 27 hemolytic Streptococcus, a coagulase-positive Staphylococcus, Aerobacter aerogenes, and Bacillus mesentericus after a clean operation. The source of the Streptococcus was not determined. A coagulase-positive Staphylococcus was found in the nose of the operating room nurse but the many possible reservoirs of staphylococci in the noses of the visitors and on the skin of those taking part in the operation were not investigated. A. aerogenes and B. mesentericus were isolated from an unsterilized roll of plaster wool. The application of a plaster over unsterilized materials may allow organisms to penetrate the sterile dressings. Plaster wool exposed on a trolley in the plaster room may be contaminated by organisms present in the air. It is suggested that efficient masks should be provided for all those present at operation. All plaster wool used under a plaster should be autoclaved and should be unwound and rolled loosely, so that it will be penetrated by steam. Plaster wool should not be exposed on trolleys either before or after sterilization.

Streptomycin in Hemophilus Influenzae Meningitis.—Eleven patients between the ages of 4 and 22 with Hemophilus influenzae meningitis were treated with streptomycin for one to 60 days. Only five had presenting symptoms suggesting involvement of the central nervous system. Three were thought to have gastroenteritis and two an upper respiratory infection. As a result, diagnostic lumbar puncture in these cases was delayed for five to 30 days after the onset of the illness. In three patients, a spinal block developed and death followed. Necropsy revealed that both cerebral hemispheres were almost covered, and the spinal cord was encased in tenacious pus. Seven patients recovered, and one patient became demented and blind. In all the patients the strains of H. influenzae isolated were type b. The organism was sensitive to streptomycin in a concentration of two to 10 units per cubic centimeter. In four patients the cerebrospinal fluid became sterile in 24 hours. No streptomycin-resistant strains developed in any of the patients. The levels of streptomycin in the cerebrospinal fluid 24 hours after an intrathecal injection of 20-50 mg. of streptomycin were four to 64 units per cubic centimeter. When upper respiratory infections are prevalent in children, it is not easy to detect that a feverish cold is due to a more serious infection. Still more difficult is it to revise an established diagnosis. Meningism and convulsive phenomena should be accorded the respect that their possible etiology warrants. Earlier diagnosis by lumbar puncture is essential if the results are to be improved.

*Heredity of Diabetes Mellitus: Question of Advisability of Marriage of Diabetic Patients. H. Thöne.—p. 327.
Local Application of Penicillin in Puerperal Mastitis with Abscess Formation H. Lüffe.—p. 332.

Heredity of Diabetes Mellitus.—The question whether it is advisable for diabetic patients to marry induced Thöne to investigate the familial occurrence of diabetes mellitus in a group of 130 diabetic patients. Forty-one (31.5%) of these patients had persons with diabetes mellitus among their blood relatives. In 15 of these patients one of the parents was diabetic (nine mothers and six fathers); in three, one of the parents as well as siblings had diabetes; in six, one of the grandparents was diabetic, whereas the parents were not; in about one-fourth of the patients siblings were diabetic, and conjugal diabetes was found in two couples. When diabetes was transmitted from parents to child, it appeared at an average age of 52, whereas when a grandparent was diabetic it became manifest at an average age of 36. Patients who have diabetic siblings usually become diabetic at about the age of 46. Anteposition was quite evident; that is, even if diabetes appeared at an advanced age in the older generation it was likely to appear earlier in the later generation. A predisposition to diabetes is hereditary, but the transmission is oftener recessive than dominant. Although the likelihood of developing the disease is much greater for a child with a familial predisposition to diabetes than for one without such predisposition, the author does not believe that a diabetic person should be forbidden to marry, at any rate, not if the partner is free from metabolic disorders. If both partners have a family history of diabetes, then the likelihood of diabetes in the offspring is great.

Depot (Slow Acting) Female Hormone Preparations in Gynecology. L. Nürnberger.—p. 453.
*Treatment of Anemia with Cobalt Compounds. H. Wolff and S. Barthel.—p. 467.

Treatment of Anemia with Cobalt Compounds.—Wolff and Barthel studied several cobalt compounds for their hematopoietic effects, possible secondary effects, and dosage in human anemia. Of 81 patients with various forms of anemia they treated 36 with intravenous injections of water-soluble cobalt chloride and 40 with intramuscular injections of an amino acid complex of cobalt. The intravenous injection of water-soluble cobalt had undesirable secondary effects in some patients, whereas the amino acid complex of cobalt was tolerated without such reactions. The latter complex is thus the preparation of choice. The reaction to dosage was tested by administration of 2.5 mg. of cobalt on the first day and 5 mg. on the second day. Thereafter, sensitive persons were given once or twice daily 2.5 mg. of cobalt, while persons with normal reactivity were given 5 to 10 mg. once or twice daily. Undesirable secondary effects were thus avoided, and treatment could be continued for the required period of 10 to 30 days. The small doses of cobalt exerted a decided erythropoietic stimulus. With the exception of pernicious anemia and macrocytic anemia, cobalt therapy is effective in almost all forms of anemia, particularly in those forms in which the bone marrow is slow to respond and requires a more potent stimulus than iron therapy.

*Insufflation of Air Under Skin as Therapeutic Method in Pleurisy. J. C. Gerrits.—p. 515.
Spinal Paroxysmal Hypertension. M. Koster, J. M. van der Valk, M. Frenkel and J. Groen.—p. 520.

Insufflation of Air Under Skin in Pleurisy.—According to Gerrits, there have been several reports in the literature concerning the effectiveness of the insufflation of about 50 cc. of air under the skin of chest or back in the resorption of the exudate in pleurisy. This insufflation was given once a week and proved entirely harmless and usually painless. The air is injected on the side of the pleuritic process and spreads over a rather large surface. It stimulates the skin and the subcutaneous tissue, and by reflex paths, the deeper organs, in this case, the pleura and lung, and it promotes the absorption of the exudate. It is suggested that cutovisceral reflexes are involved in this mechanism. So that the needle will not enter a blood vessel and cause an air embolism, suction is applied with the syringe plunger. The author used this treatment in 17 patients with exudative pleurisy. The treatment was ineffective in five of the patients, and in the others the absorption of the exudate was greatly or moderately stimulated and accelerated.

Death Following Intravenous Urography. K. Fischermann and J. Ostenfeld.—p. 240.

Gastric Insufficiency: Diagnosis, Sequelae, and Treatment.—Forsgren says that the results of a single Ewald test breakfast will often be misleading, and the test breakfast should be supplemented by a test dinner containing meat, which, with its buffer action, is calculated to show the insufficiency of a small secretion of gastric juice produced by excitation with histamine; the addition of cubes of coagulated egg white will facilitate evaluation of the degree of digestion. The frequency of achlorhydria increases with age and will be a grave problem in geriatrics. Malnutrition of gastrogenic kind may lead to pernicious anemia, myelopathy, epithelial symptoms, and impairment of the phagocytic defense against infections. The author estimates that the incidence of tuberculosis is about 10 times as high in persons in whom gastrectomy has been done as in the general population. Gastric insufficiency can be compensated in high degree by carefully prepared food and a physically and mentally hygienic mode of life. Diarrhea and meteorism due to gastric insufficiency as a rule respond to treatment. Concentrated liver preparations and vitamin B are indispensable in the treatment of pernicious anemia and myelopathy. In total achlorhydria an attempt should be made by hydrochloride acid administration to restore the normal pH in the alimentary tract and normalize the bacterial flora in the gastroduodenal segment. Gastrogenic damages to the nervous system are not always wholly reversible, and therefore treatment should be begun early. A psychogenic gastric insufficiency is reversible, at least at an early stage; psychotherapy and antiachylic treatment are important. Treatment of gastric insufficiency after stomach resection often entails great difficulties. The resources for compensating postoperative gastric insufficiency are limited.

Hemangioma of Kidney. K. Liavaag.—p. 276.

Hyperparathyroidism.—Hyperparathyroidism is characterized primarily by a disturbance in calcium metabolism. The most pronounced symptoms are skeletal calcification, usually in the form of so-called osteitis fibrosa generalisata, and calcium deposits in the kidneys. The prognosis after parathyroidectomy depends mainly on the degree of renal damage at the time of operation. Some improvement in renal function is possible after parathyroidectomy, but the damage usually remains or progresses. Evaluation of the prognosis requires a long observation period, as patients may apparently be well for many years but ultimately die from sequelae of the hyperparathyroidism. Renal injury is an early sign of the disease; it is ascribed to calcium deposits in the tubular epithelium and to vascular changes and is expressed by hyposthenuria and polyuria. There is usually increased blood pressure, which becomes more and more manifest and is an important cause of the unfavorable prognosis. Since early diagnosis and operative treatment are of decisive importance, the possibility of hyperparathyroidism should be borne in mind in cases of renal calculus, especially in multiple bilateral concrements, and examination of the blood calcium should be made in all patients with symptoms that might depend on hyperparathyroidism. Parathyroidectomy is the only treatment to be considered. Radiotherapy is ineffective and delays operation. Excision of the affected gland suffices in the case of adenoma. In diffuse hyperplasia, resection should be as complete as possible without risk of tetany, but partial parathyroidectomy may result in improvement. There were skeletal changes in eight of the 23 cases of hyperparathyroidism, renal calcification in nine, and both symptoms in six cases. Follow-up examination of 10 patients with solitary adenoma more than two years after the operation showed that the general condition and ability to work were often good for years, and in five patients with solitary adenoma operated on in 1950 the immediate result is excellent, but only one patient has normal renal function. The five patients with diffuse hyperplasia operated on showed improved general condition and ability to work despite continued increased blood calcium: of the four observed for over 10 years one died from uremia, two are disabled because of hypertonia, and one patient is still able to work.

Subdural Tapping.—Subdural hematoma is ascribed to trauma of the head during birth or later; this trauma may be slight and unnoted. Subdural tapping has been performed in the children's department of the Rikshospital since 1947 in the diagnosis and treatment of subdural hematoma. Vesterdal and Walther report 248 punctures, 201 for diagnostic and 47 for therapeutic purposes, in infants aged from 1 day to 19 months. Effusion of cerebrospinal fluid into the subcutaneous tissue occurred in many cases but was without significance; no other side effects were noted. Pathological fluids were found in 12 cases. In the five cases described, subdural hematoma was confirmed at operation. One patient died before further examination could be made, in two patients ventriculography failed to disclose subdural hematoma, and in four operations revealed other intracranial hemorrhage or hydrocephalus. The authors warn that since there may be a wide, free zone between the hematoma and the midline the tapping should be done as laterally as possible. Diagnosis of subdural hematoma on the basis of clinical symptoms alone is extremely difficult or impossible, and subdural tapping should therefore be used together with lumbar puncture in the examination of infants with obscure cerebral symptoms.

Paper Chromatography of Urine in Pregnancy and Preeclampsia.—Dent's modification of paper partition chromatography for qualitative analysis of free amino acids in the urine was used by Zilliacus for identification of histidine in the urine of nonpregnant women, in normal pregnancy, and in pregnancy complicated by toxemia. He finds his results support earlier observations that no histidine or only traces of histidine appear in the urine of nonpregnant women, that histidine in the urine is the rule in normal pregnancy, and that histidinuria decreases or disappears in patients with symptoms of toxemia of pregnancy. The absence of histidine in the urine in a patient with toxemic hydatid mole suggests that placental or endocrine factors are involved in the disappearance of histidine from the urine in toxemia of pregnancy.

*First Cases of Cure of Primary Pneumonic Plague Obtained with Streptomycin. F. Estrade.—p. 328.

Streptomycin in Primary Pneumonic Plague.—Two patients, a man, 19, and a woman, 25, with primary pneumonic plague, were treated with streptomycin on the island of Madagascar. The total dose of the drug over a six day period was 25.75 gm. With this relatively small dose, Pasteurella pestis was still present in the sputum of the patients 20 hours after the institution of the treatment but the organisms had lost much of their virulence and were no longer capable of killing guinea pigs. Temperature was restored to normal on the sixth day, and the patients were convalescent. It appears that in vivo streptomycin rapidly effects the virulence of the pathogenic agent before a bacteriolytic action can be manifested. Systematic roentgenologic examination was made of the female patient before treatment and on the second and eleventh days after the institution of treatment. Characteristic foci of confluent bronchopneumonia were observed at the first examination; some clearing was noticeable at the second examination, and complete clearing was observed at the last examination. The therapeutic success, the economy of the therapy, and the fact that the contagious period of the patient has been limited to a short time are to be considered of greatest importance in pneumonic plague. Antiplague serum therapy, previously practiced in Madagascar, failed to cure pneumonic plague, and streptomycin was the only drug with which a cure was obtained. Systematic roentgenologic examination of persons who have been exposed to the infection may be a means of early diagnosis of pneumonic plague.

Sjögren's Disease.—The occurrence of Sjögren's disease in a woman 34 is reported. She complained of dryness of eyes, mouth, and throat, and a dry cough aggravated by talking. Symptomatic treatment of the eyes with cod liver oil drops gave symptomatic relief. Attempts to increase the salivary secretion by pilocarpine, acetyl-beta-methylcholine chloride and physostigmine were unsuccessful. For alleviation of the dryness of the bronchial mucosa, the patient was kept for two weeks in a steam tent. This had no beneficial effect on the respiratory condition but seemed to have aggravated the patient's arthritis. A spontaneous pneumothorax developed on the right side, associated with dyspnea and cyanosis. Silver nitrate pleurodesis produced gradual adhesion of the pleural surface of the right lung. However, a gradual downhill trend developed. Death resulted from acute bronchopneumonia. Necropsy was performed, and microscopic examination of the lacrimal, parotid, and sublingual glands, of the conjunctival, buccal, nasal, and nasopharyngeal mucosa, and of the mucosa of the epiglottis, larynx, trachea, bronchi, esophagus, and their subjacent secretory glands confirmed the view that the pathological basis of the dryness of the mucous membranes and skin consists of a chronic inflammatory atrophy of unknown causation involving the salivary, lacrimal, mucosal, and sweat glands. This dryness may give rise to obstructions in the parotid and salivary glands and in the bronchial tubes, resulting in a secondary inflammatory granulomatous process and possibly suppuration.

Felty's Syndrome.—The results of splenectomy in four patients, one man and three women, with Felty's syndrome are reported on. All the patients had the characteristic triad of rheumatoid arthritis, splenomegaly, and neutropenia. There was an interval of five years between the onset of arthritis and the development of splenomegaly and leukopenia in two patients, and an interval of about 20 years in the two other patients. The arthritis was therefore advanced, and permanent deformities of some joints were present. The preoperative blood picture of all the patients showed anemia. The white blood cell count varied considerably, but in each case it was well below 3,000 per cubic millimeter at its lowest. Severe buccal ulceration often associated with neutropenia was a distressing feature in two patients. Splenectomy led to rapid cure of the ulcers in the mouth. Only one patient showed definite, measurable improvement in the joints, and the results made it clear that splenectomy should not be regarded as a treatment for the joint condition itself. There was an immediate postoperative increase in white blood cells in every patient, which was maintained for over a year. In every case the most striking feature was the improvement of general health. Felty's syndrome is probably merely a peculiar variant of rheumatoid arthritis and not a separate entity. Neutropenia, on which most emphasis was laid, is entirely secondary to hypersplenism, which may occur in any disease in which splenomegaly is a feature. The authors feel that, provided there are no associated diseases that would contraindicate surgical intervention, splenectomy should be performed in all cases. The resultant restoration of the white blood cell count to normal clears up the associated infective processes and improves the general health of the patient.

*Carcinomas of Mouth and Pharynx Treated from 1928 to 1945: V. Results of Roentgenotherapy of Carcinomas of Hypopharynx (37 Cases). Clinicostatistical Study. B. Antoniazzi.—p. 35.

Roentgenotherapy of Carcinoma of Hypopharynx.—The author reports results of roentgen therapy in 37 cases of cancer of the hypopharynx. The group included 35 men and two women. Most of the patients were over 50. The cancer was advanced in all cases. It was located in the upper larynx in 15 cases and in the lower half in 22 cases. A biopsy was made in 20 cases. It showed spinocellular cancer in 17 cases and basocellular cancer in three cases. The treatment consisted of local roentgen therapy of the cancer lesion and the regional lymph nodes followed by ample removal of all the metastatic regional lymph nodes. The author describes the technique, dosage, and duration of the roentgen treatment. In the cases reported the hypopharyngeal cancer was vegetating in 11 cases, infiltrating and vegetating in 13, and infiltrating in 13. Metastases in the regional lymph nodes were encountered in 16 patients, six with cancer in the upper larynx and 10 with cancer of the lower larynx. The metastases were unilateral in 13 cases and bilateral in three. Neither contralateral lymph node nor visceral metastases were observed, although no necropsies were done. The four patients living five years after discontinuation of the treatment are normal, without any recurrence of cancer.

*Treatment of Trichomoniasis Vaginalis with Tyrothricin. J. M. Sánchez Ibáñez.—p. 15.

Treatment of Trichomoniasis Vaginalis with Tyrothricin.—Five cases of trichomoniasis vaginalis were treated by the author with a powdered mixture of 50 mg. of tyrothricin and 100 gm. of boric acid with good results. All patients were married women; one was pregnant. All had leukorrhea and acute pruritus vulvae. Gonococcus and cervical erosion were present in one patient and staphylococcus in another. Treatment consisted of a vaginal douche with 5% lactic acid and insufflation of the tyrothricin-boric acid mixture into the vagina, every other day. Bacteriologic examination of vaginal smears became negative in all cases after the first application of the drug. The treatment was given at least four times. Patients were considered cured after three monthly bacteriologic examinations of vaginal smears following the menstrual period gave negative results. The author advocates the powdered form of tyrothricin, because of its easy application and stability in the vaginal cavity and cul de sac, without inconvenience to the patient. Tyrothricin therapy significantly shortens the course of treatment as compared with other drugs.

Question of Origin of Resistance of Mycobacterium Tuberculosis to Streptomycin. P. Zadik.—p. 281.
*Treatment of Pertussis with Chloramphenicol and Aureomycin. F. Buser.—p. 282.

Chloramphenicol and Aureomycin in Pertussis.—Forty-two patients with pertussis, 23 between 1 and 4 years old, 16 between the ages of 4 and 7, and three adults, were treated with chloramphenicol (chloromycetin®). Treatment was instituted at the beginning of the paroxysmal stage. The patients did not receive antipertussis serum before they were given chloramphenicol. The antibiotic was given by mouth in doses of 50 to 60 mg. per kilogram of body weight daily for four to eight days. Chloramphenicol aerosol was administered to five patients with an inhalation apparatus three to four times daily for 10 minutes. Twenty patients with pertussis, four nursing infants, 11 children between the ages of 1 and 4, and five between the ages of 4 and 7 were treated with aureomycin. For six to eight days, 25 mg. of the drug per kilogram of body weight was administered daily. Both chloramphenicol and aureomycin favorably influenced the course of the disease and the number and severity of the paroxysmal attacks. Neither drug caused untoward reactions, and there was no distinct difference between their effectiveness. A comparison of graphic recordings of the paroxysmal attacks of cough in patients with pertussis treated with antibiotics (chloramphenicol and streptomycin) or human pertussis immune serum revealed that similar satisfactory results were obtained with both the therapeutic methods. Chloramphenicol and aureomycin had a somewhat more rapid effect than streptomycin. The immune serum is considered superior to any other therapy in infants with severe toxic pertussis associated with attacks of asphyxia, while the antibiotics seem to be more reliable in bronchopneumonia associated with pertussis. Combined treatment with antibiotics and human pertussis immune serum seems to be advisable in infants and children with severe pertussis.

Excision of Large Superficial Petrosal Nerve and Cephalic Forms of Neurovascular Disease. J. N. Taptas.—p. 787.
Attempt to Treat Delayed Mental Development in Children by Jugulocarotid Anastomosis. M. R. Klein, J. Lepintre, G. Tardieu and J. P. Held.—p. 792.
*Cerebral Scars in Children. M. R. Klein, J. Lepintre, G. Tardieu and R. Galez.—p. 796.

Cerebral Scars in Children.—In a cerebral scar there is a diffuse fibrous neuroglial hyperplasia, which tends to spread into the subcortical area and toward the ventricle, exerting an inhibitory effect on the neighboring and distant healthy tissue. The site and extent of the scar may be ascertained by clinical investigation, electroencephalographic recordings and ventriculography. Hemiplegia, epileptic seizures and delayed mental development, occurring independently or together, are the main neurological syndromes produced. Surgical excision or undercutting of the scar was performed by the authors on 50 patients in whom delayed mental development was associated with hemiplegia or epileptic attacks or both. Thirty-seven patients were followed up for several months to three years. Eighteen patients showed definite improvement, 17 were unchanged and two died, one within several hours after the operation and one within seven days. Eighteen of 33 patients with hemiplegia and three of 26 with epileptic seizures were improved, with one possible cure. Three of 23 patients with delayed mental development were improved, with an increase of about 10 in the intelligence quotient. Ten of 16 patients with a scar limited to the white matter exclusively showed improvement. None of the four patients in whom the scar had spread to large areas of the cortex were improved. Eight of 17 patients with involvement of the subcortical area showed improvement. Six of eleven patients with a scar in the rolandic area and seven of nine patients with a scar in the frontal region were improved. Five of 14 patients with a scar in the parietal region showed improvement. Treatment failed in two patients with a scar in the occipital region and in one patient with a scar in the temporal region. The operative technique varied according to the site and the extension of the scar. Total excision of the scar was performed when it was limited to a small area, while subcortical cutting without excision of an extensive scar was done in 14 instances to isolate the lesion from the healthy tissue. Definite improvement resulted from the latter intervention in 10 instances. The risk associated with surgical treatment is to be considered minimal despite the importance of the operation, and the reported results are believed to be satisfactory and encouraging.

Present State of Means of Study of "Essential Epilepsy" on a Symptomatic Basis. J. Guillaume, G. Mazars and Y. Mazars.—p. 865.

*Present State of Surgical Treatment of Epilepsy. J. Guillaume, G. Mazars and Y. Mazars.—p. 871.

Neuroendocrine Syndromes and Ventricular or Cisternal Hydrops. J. Guillaume, R. Rogé and R. Djindjian.—p. 876.

Surgical Treatment of Epilepsy.—Of 78 patients with focal epilepsy who were subjected to excision of the cortex under electrocorticographic control, only 11 were found to have an epileptogenic focus with a brachial or crural motor or sensory localization, while 42 had a temporal or insular focus, and 14 a frontal focus. Clinical observations thus would have permitted a definite localization in only one-seventh of the patients. The authors have abandoned the classic procedure of electrical stimulation of the brain for establishing the topography of the cortical lesions. They prefer localization by means of electrocorticographic recording with the use of eight articulated electrodes placed in lines on the exposed cortex. The motor cortex is characterized by an electrical activity consisting nearly exclusively of beta waves, so that it can be identified without the aid of electrical excitation. The method of extending the cortical excision until any abnormal electrical activity has disappeared appears to be the most reliable one for the surgical treatment of focal epilepsy. It is indicated in patients with severe epileptic attacks that occur frequently and are not completely controlled by medication and in patients in whom disturbances of character persist despite the disappearance of the attacks. Thirty-two patients operated on according to this method were followed for two years. According to Penfield's criteria, good to excellent results were obtained in 21 of these 32 patients (64%). Medication could be discontinued within several weeks of the operation without inconvenience in seven of the 32 patients. One patient who before the operation had agoraphobia and attacks of aura vertiginosa was able to resume his former profession as a traveling salesman. A child who before the operation had been placed in an institution for incurable children did not have any attacks for two years after the operation, was able to attend school regularly, and no longer required medication. In one patient Jacksonian attacks in the lower extremity disappeared completely, and there was no secondary motor disturbance, although the epileptogenic focus was located adjacent to the paracentral lobule. Highly satisfactory results were obtained with the excision of the insular cortex in nine patients, none of whom had any attack after the operation. Recovery without sequelae was obtained also in patients with severe neurovegetative disturbances. In six patients the character disturbances disappeared simultaneously with the epileptic attacks, but these disturbances persisted in three others despite the disappearance of the attacks. In a number of patients attacks could be controlled by drugs to which the patients had not responded before the operation. In certain cases reoperation may be preferred to an extensively and perhaps unnecessarily mutilating first intervention.

Whooping Cough Epidemic in Urban Native Location. H. T. Phillips. —p. 110.

*Double Duodenal Ulcer with Perforation Following Burn. M. R. Mynhardt.—p. 1[illegible].

Double Duodenal Ulcer Following Burns.—Mynhardt reports the case of a woman, 34, who sustained second and third degree burns, involving 60 to 64% of the body surface, when her clothing caught fire. Petrolatum gauze and pressure dressings were applied. Penicillin and streptomycin were given. Shock was combated by blood and serum transfusions and by other intravenously administered fluids. The diet was high in proteins and vitamins. When contracture deformities of hips and feet began to develop, a plaster bed was constructed. Except for occasional small rises in temperature the patient progressed favorably for several weeks. Then she began to deteriorate rapidly; abdominal tenderness and signs of peritonitis developed. There was temporary improvement following treatment with aureomycin, penicillin, vitamin K, heparin, and a digitalis preparation, but then signs of hypostatic pneumonia appeared, and death followed. At necropsy a Curling's ulcer approximately ¾ in. (1.91 cm.) long and irregular in shape was found 1 in. (2.54 cm.) distal to the pyloric sphincter on the anterosuperior wall of the first part of the duodenum. The ulcer had perforated but was sealed off by omental adhesions. A blackish discoloration (due to local thrombosis) around the edge of the ulcer was a prominent feature. A more circular, unperforated ulcer was present in the second part of the duodenum. The history, etiology, and histopathology of Curling's ulcer are discussed. The most widely accepted theory of the etiology of this ulcer is that it results from local thrombosis, which in turn is caused by the toxemia and sepsis associated with burns.

Evolution of Therapy of Urethritis. L. Sylvestre.—p. 183.

Treatment of Nontuberculous Diseases with Streptomycin. J. Prévost. —p. 187.

Thyroidectomy. C. E. Grignon, R. Grignon and J. Grignon.—p. 193.

Diagnosis and Treatment of Syphilis.—The use of penicillin has profoundly changed the treatment and the prognosis of syphilis. In the majority of the cases, early infection yields to a total dose of 5,000,000 to 6,000,000 units of penicillin administered in the course of 10 days. Institution of this treatment during pregnancy almost certainly prevents the congenital infection, and it greatly simplifies the treatment of late syphilis. Neurosyphilis, if diagnosed in the preclinical period or before irremediable destruction of tissues has occurred, may in general be arrested by repeated courses of penicillin, and malaria therapy may be required in only a few particularly resistant cases. A positive qualitative reaction of the blood, the cerebrospinal fluid or both to the various tests should not be considered sufficient for establishing the diagnosis or prognosis of syphilis. Quantitative serologic tests and a thorough evaluation of the clinical manifestations are indispensable. In cases of late syphilis, the disease process can be definitely checked and the spirochetes completely destroyed while the blood or even the cerebrospinal fluid still gives positive reactions to the Wassermann or Kahn tests. Consequently, an isolated positive reaction to a serologic test is not necessarily an indication of active infection that requires treatment. The serologic curve, the duration of the infection and the total amount of treatment received represent the essential considerations for the institution, conduct and discontinuation of treatment of syphilis.

BOOK REVIEWS

Yellow Fever. Edited by George K. Strode, M.D., Director, International Health Division, Rockefeller Foundation, New York. Cloth. $9.50. Pp. 710, with 77 illustrations. McGraw-Hill Book Company, Inc., 330 W. 42nd St., New York 18; Aldwych House, Aldwych, London, W.C.2, 1951.

This distinguished volume is not a history of yellow fever of olden days, with its frequent epidemic visitation during the 18th and 19th centuries to the east coast and gulf ports of the United States and to the cities of Southern Europe. Nor is it a narrative of the discoveries, made by Finlay, by Reed and his colleagues and by Gorgas, of the etiology, epidemiology, and control of urban yellow fever. While these dramatic events are briefly considered in their appropriate setting, this book is primarily an account of the investigations of the Rockefeller Foundation. During the period 1916-1949, 422 articles on yellow fever were published by staff members of the Foundation, which made a financial contribution of nearly 14 million dollars to carry out these projects.

Following a preface by Dr. Strode, there are 10 separate sections, each consisting of several closely related chapters, viz., (1) Landmarks in the Conquest of Yellow Fever, (2) The Virus, (3) Pathology, (4) Immunology, (5) Arthropod Vectors, (6) Mammalian Host, (7) Clinical Aspects and Diagnosis, (8) Epidemiology, (9) Control, and (10) Costs and Man Power. All of this information has been woven together into an unusually lucid narrative. Even the most technical material is clearly presented. Written by experts, the data are authoritative and are probably as objectively presented as is humanly possible. Although no attempt has been made to provide an exhaustive treatise, the facts presented are quantitatively impressive, while the findings constitute valuable scientific knowledge and at the same time important landmarks in the prevention of the disease.

Briefly considered, the most significant developments in the campaign against yellow fever from 1916 to the present time have been twofold. In the first place, while effective control of Aedes aegypti, the vector of epidemic urban yellow fever, eliminated the danger of outbreaks in nontropical areas as in the United States, it did not provide the same degree of safety for cities in South America or tropical Africa. Marginally rural epidemics developed which at times spread to the cities. Fundamentally, yellow fever was found to be a disease not of human populations but of dense tropical forests, where it is enzoötic and epizoötic among monkeys and at times other mammals, and is transmitted by sylvatic mosquitoes. Human entry into these enzoötic areas or the egress of infected semidomestic mosquitoes or marauding monkeys from the jungle into near-by rural habitations provides the opportunity for human exposure. Thus, effective control of Aedes aegypti in the tropics does not eliminate yellow fever.

The second fundamentally important discovery consisted in the development of a safe vaccine to protect persons likely to be exposed to the disease. Between 1940 and 1947, more than 28 million doses of vaccine were prepared and distributed by the Yellow Fever Laboratory of the Rockefeller Foundation in New York City, while other laboratories furnished additional amounts. Moreover, growing out of the immunologic studies the mouse protection test made it possible to determine whether immune bodies had developed in vaccinated subjects; likewise, by surveying populations in extensive areas adjacent to known enzoötic zones, epidemiologists were able to determine how far the disease had extended from the sylvatic foci. Similarly, the test has been useful in discovering which mammals in the sylvatic foci had had, or are susceptible to the infection.

Undoubtedly these discoveries would have been made eventually had not the Rockefeller Foundation entered into the problem. Dr. Strode and his colleagues give generous credit to the many independent and associated investigators who have concurrently contributed to the elucidation of the questions which required solution. Nevertheless, the professional and financial support of the Foundation provided expert coördination and guidance, as well as momentum.

The volume is faultlessly written and beautifully printed. Included are an excellent bibliography and a very satisfactory combined subject-author index. The heavy linen cover is well adapted for hard use. One error which has been noted is the use of the term "endemic" instead of "enzoötic" in reference to the sylvatic infection.

Rest and Pain. By John Hilton, F.R.S., F.R.C.S. Edited by E. W. Walls, M.D., Ch.B., B.Sc., Professor of Anatomy in University of London at Middlesex Hospital Medical School, and Elliot E. Philipp, M.A., M.B., B.Chir., Honorary Demonstrator in Anatomy at Middlesex Hospital Medical School, London, in collaboration with H. J. B. Atkins, D.M., M.Ch., F.R.C.S., Director of Department of Surgery, Guy's Hospital, London. [Originally issued in 1863 with title: On the Influence of Mechanical and Physiological Rest in the Treatment of Accidents and Surgical Diseases, and the Diagnostic Value of Pain.] Sixth edition. Cloth. $8. Pp. 503, with 105 illustrations. J. B. Lippincott Company, 227-231 S. 6th St., Philadelphia 5; Aldine House, 10-13 Bedford St., London, W.C.2; 2083 Guy St., Montreal, 1950.

This is a presentation of a lecture series delivered at the Royal College of Surgeons in the middle of the nineteenth century. A surgical classic, this book has been revised and reprinted many times. There are numerous notes by the editors, which add a modern interpretation to the observations of Hilton.

This book is written in a charming and informal manner. It is replete with case histories presenting symptoms and their interpretation, anatomy, pathology, and treatment for a wide variety of diseases. In many instances, one is amazed at the difference between nineteenth and twentieth century concepts of medicine. The principal theme that recurs throughout the volume is that simple rest would benefit or cure a great many diseases. An important task of the physician is to recognize disease and to place the involved portion of the body at rest. Another point that is stressed is that rest is not harmful to normal portions of the body.

Modern physicians often fail to realize the change that has taken place in medicine within the preceding half-century. Reading this volume must increase one's admiration for the physicians of the past, who were able, without present laboratory and pharmacologic aids, to accomplish so much in the care of the sick.

Soil and Freshwater Nematodes: A Monograph. By T. Goodey, O.B.E., D.Sc., F.R.S., Head of Nematology Department, Rothamsted Experimental Station, Harpenden, Herts. Cloth. $7. Pp. 390, with 191 illustrations. John Wiley & Sons, Inc., 440 4th Ave., New York 16; Methuen & Co., Ltd., 36 Essex St., Strand, London, W.C.2, 1951.

Most physicians whose practice includes the diagnosis and treatment of common nematode diseases are probably unaware that the roundworm parasites of man and domestic animals comprise only a small segment of the total species of nematodes in the world. By far the largest number are free-living, in soil and freshwater. Some are distant kin to the trichina worm (Trichinella spiralis) and the whipworm (Trichocephalus trichiurus); others are more nearly related to Strongyloides and the hookworms. Certain free-living nematodes, for example, species of Rhabditis, Rhabditiella, Turbatrix (the "vinegar eel"), Ditylenchus (the "onion bulb nematode"), and Heterodera (the "root-knot nematodes") have been found as contaminations of human feces, urine, or even skin lesions, and thus require diagnostic differentiation to eliminate them as potential agents of human disease.

The author of this monograph is one of the few world authorities in his field. He has provided the first up-to-date comprehensive manual on the subject, which is necessarily technical. After a short résumé of approved technics for collecting free-living nematodes and preparing them for

---

The reviews here published have been prepared by competent authorities and do not represent the opinions of any official bodies unless specifically stated.

characteristics of these worms are described; then all the known genera are systematically presented, with a description of the type species (or other better known species) of each genus, and the names of the other species of the genus are listed. For the more common species there is brief bionomic information, including the geographic locations where the organisms have been found.

As a minor criticism it may be pointed out that some of the genera included in this monograph are primarily parasites of plants and as such are important in agriculture and horticulture, while their free-living stages in the soil are relatively incidental. Strongyloides and hookworms likewise have such a free-living stage in the soil. Furthermore, the monograph would have been more comprehensive if the larval stages of these worms had received brief consideration.

Excellent figures add much to the usefulness of the text. The type is clean, and the format is unusually pleasing. The book is substantially bound. It constitutes a valuable companion volume to Goodey's "Plant Parasitic Nematodes and the Diseases They Cause" (1933) and will be welcomed as an important contribution to invertebrate zoology.

A History of Nursing. By Gladys Sellew, Ph.D., R.N., Chairman of Department of Sociology and Social Work, Rosary College, River Forest, Ill., and C. J. Nuesse, Ph.D., Assistant Professor of Sociology, Catholic University of America, Washington, D. C. Second edition. Cloth. $3.75. Pp. 439, with illustrations. C. V. Mosby Company, 3207 Washington Blvd., St. Louis 3, 1951.

This edition, like the first, has as its central thesis the inextricable interweaving of nursing service with all other branches of human culture. This revision remains unaltered in general philosophy. The authors retain the conviction that nurses can gain insight into their own roles through study of professional history in the light of social history.

Aspects which are considered include the relationship between social and cultural systems and health and disease, the emergence of an art of nursing among primitive people, and the advances and regressions of nursing as a result of the spiritual revolution of Christianity, the fall of Rome, the Protestant revolt and the humanitarian movement. The founding of the nursing profession by Florence Nightingale, its worldwide extension, with particular emphasis on its background, beginning, and expansion in the United States, are discussed. Considerable attention is given to the development and present status of nursing education.

This book points out not only service rendered by the nursing profession but also the socioeconomic changes through the ages that have given stimulation and direction to its development. This approach is in accord with the persistent efforts of nursing educators toward the concept that the patient and his environment are inseparably related factors in nursing care.

Retire and Be Happy. By Irving Salomon. Cloth. $2.95. Pp. 205. Greenburg, Publisher, Inc., 201 E. 57th St., New York 22, 1951.

This book contains considerable material of interest to persons about to retire, but its scope and interest are limited to those able to retire with considerable financial provisions. Although the author denies that one must be provided with an adequate income, all his criteria for successful retirement are based on the assumption that this is indeed the fact. Many will differ with the author's conclusion that a man should retire and cease making money as soon as he is able, even if this happens in his thirties or forties rather than in the more usual sixties and seventies. While decrying the needless making of money, the author nevertheless cites with apparent approval a number of instances in which hobbies have turned into lucrative occupations for the retired. The book contains too many glib assumptions, such as that a planned retirement assures a happy retirement and vice versa. In his chapter on philosophy and religion, he has stepped so gingerly to avoid offending any specific philosophic or religious groups that he ends up with a conglomeration of vague nothingness. He devotes a chapter to health, but acknowledges that it contains little or nothing because "this is a topic to be left to the medical profession."

The book is ostensibly based on a casual study of 405 retired persons, apparently all men. The material itself is rather slender to form the basis of a book, and this makes the entire manuscript repetitious and wordy. The editing is careless, exhibiting a number of instances of plural subjects with singular verbs and similar evidences of loose writing. This book is a useful effort which does not quite achieve excellence.

Annual Review of Physiology. Volume XIII. Victor E. Hall, editor, Jefferson M. Crismon and Arthur C. Giese, associate editors. Cloth. $6. Pp. 457. Annual Reviews, Inc., Stanford, California, 1951.

This volume, like the preceding ones, presents a series of papers on the current status of various topics in physiology. Each paper is written by an authority in the field. The majority of the contributors are from American laboratories; four of the papers are by European scientists. D. K. Hill of the University of London, in collaboration with A. V. Hill, has written on muscle, dealing particularly with muscle proteins and the biophysics of muscular contraction. Gestaut of Marseille has contributed a section on the electrical activity of the brain. Moruzzi of the University of Pisa has reviewed the somatic functions of the nervous system, while Runnstrom and Gustafsun of the University of Stockholm discuss developmental physiology, with particular emphasis on the biochemical approach to morphogenesis. In the discussion on permeability, the importance of distinguishing between simple diffusion, complex formation, and active selective transport is stressed. The effects of ionizing radiations on living systems are capably discussed, and the current status of certain aspects of thermophysiology is presented. Separate papers deal with the digestive system and with the liver, the latter paper placing particular emphasis on the histophysiology of the liver cell. Discussions are also devoted to other fundamental subjects, such as peripheral circulation, respiration, heart, kidney, conduction and transmission of nerve impulses, and blood volume. As might be expected, the discussion of the endocrine glands centers largely on the anterior hypophysis and the adrenal cortex, while the hypophysis and the sex hormones receive additional attention in the discussion of the physiology of reproduction. A pleasing aspect of the book is the prefatory chapter, by C. J. Wiggers, in which the author, on the basis of personal experience, interprets the influences that have aided the development of physiology during the past 50 years. This book should be of value to the reader interested in a well-documented and authoritative presentation of current trends in physiology.

Diseases of the Heart and Circulation. By Paul Wood, O.B.E., M.D., F.R.C.P., Director, Institute of Cardiology, London. Cloth. $12.50. Pp. 589, with illustrations. J. B. Lippincott Company, 227-231 S. 6th St., Philadelphia 5; Aldine House, 10-13 Bedford St., London, W.C.2; 2083 Guy St., Montreal, 1950.

This book, originally prepared in 1950 for distribution in England, has been reprinted for distribution in the United States. In it, the author attempts to cover the subject matter systematically, based on knowledge gained especially at the British Postgraduate Medical School, at the National Heart Hospital (London), and at the Rheumatic Fever Center at Taplow. He is in a sense, therefore, presenting his interpretations of the points of view of these important centers of British cardiology as well as those gleaned from the literature and his own experiences. This should be of considerable merit to the American reader, who, by comparing this British point of view with the traditional American one, may find some of the differences of value.

The subject matter is comprehensively covered. The style is clear and simple, the format pleasing and the illustrations ample, although at times one has the feeling that the author is presenting too many electrocardiograms (at times, seemingly all he has on a subject) for a book of this sort. The author brings in a great deal of the newer knowledge. For example, data procured with catheterization are well documented, so that the chapter on congenital heart disease is particularly well covered. The chapter on traumatic lesions is excellent and brings out certain facts that are sometimes neglected in many American textbooks. Obviously the presentation will not accord in all instances with American teachings, although the author is cognizant of the recent developments on this side of the Atlantic. This book is highly recommended as a worth while addition to the libraries of internists and cardiologists.

QUERIES AND MINOR NOTES

IMMUNIZATION DURING POLIOMYELITIS SEASON

To the Editor:—*I would like references on diphtheria immunization and other immunizations as related to poliomyelitis. Should immunizations be carried out during the "polio" months?* *D. C. Badger, M.D., Hobbs, N. Mex.*

Answer.—The Journal of Sept. 16, 1950, contains an editorial (page 240) and a letter from Dr. James P. Leake (page 259) in which earlier references on this subject are cited. Since then Anderson and Skaar (*Bull. Univ. Minnesota Hosp. and Minnesota M. Foundation* 22:359-370 [March 9] 1951) have published a study of data from the Minnesota outbreak of 1946. Their observations are similar to those reported in the British and Australian studies. Another recent reference is "Discussion on Poliomyelitis Following Inoculations," Section of Epidemiology and State Medicine (*Proc. Roy. Soc. Med.* 43:775-782 [Nov.] 1950). The editorial cited states, "In view of available evidence it might be advisable to postpone diphtheria and/or pertussis immunization during a poliomyelitis epidemic." During the "polio season," however, immunization has not been proved to entail any added risk to subjects in communities that are at the time free from poliomyelitis.

EYE INFECTION FROM A CORNSTALK

To the Editor:—*A patient abraded his right eye with a cornstalk about six weeks ago. I was unable to obtain a culture from the cornea, but I have obtained a fungus from the anterior chamber by paracentesis. This fungus has been identified as Paecilomyces after growth on proper mediums. He has had various types of antibiotics and chemotherapeutic agents locally and parenterally. While the wound was cauterized when first seen, the infiltration has spread over and through the cornea. The patient is at present receiving potassium iodide by mouth and sodium iodide intravenously. The pathologist says that Paecilomyces is a contaminant and not pathogenic, but the condition of the patient's eye is severe.*

M.D., Alabama.

Answer.—Paecilomyces is such a common contaminant on the special culture medium for fungi that the etiological significance of your finding seems questionable, especially since (1) cultures from the cornea have been negative and (2) the clinical course of the keratitis as described is not characteristic of fungus infection. It would seem more likely that the keratitis is due to a pathogenic bacterium or virus not easily demonstrated by culture. If it is not too late for any further attempt at constructive therapy, more intensive topical administration (by means of cotton pledgets placed on the cornea, eye baths or iontophoresis) of, alternately, an antibiotic and a sulfonamide could be tried.

TYPHOID VACCINATION

To the Editor:—*I would like information on dosage of the intracutaneous typhoid vaccination and its efficacy in comparison with the standard subcutaneous technic.*

H. B. Eisenstadt, M.D., Port Arthur, Texas.

Answer.—Intracutaneous inoculations for typhoid immunization have been reported favorably. For the "rapid method," injections are made every other day. The doses are 0.1 cc., 0.2 cc., 0.3 cc., and 0.4 cc. (a total of 1.0 cc.). It was reported by Naumer and Nerb (*Arch. Pediat.* 60:63 [Feb.] 1943) that within one week after the initial intracutaneous injection of typhoid vaccine, agglutinins appeared and that they reached their peak at three weeks. Subcutaneous inoculations give similar results.

CIGARET SMOKING

To the Editor:—*An asthmatic patient, who has not had an attack for over a year, desires permission to continue smoking. Does a cigaret holder make the cigaret less harmful? Can you suggest the cigaret that is the least harmful?*

M. B. Daitch, M.D., Santa Monica, Calif.

Answer.—Asthmatic attacks may be precipitated, or aggravated, by smoking, as a result of the physical irritation of the hot, particle-laden smoke; the chemical stimulation of the nose, the upper respiratory passages or the bronchi, by the ammonia in the sidestream smoke or the aldehydes, the tars or the nicotine in the mainstream smoke, with reflex bronchial contraction. More specific bronchoconstriction may attend allergic reaction to tobacco, probably to antigenic proteins in the tobacco, or the pharmacodynamic effect of the nicotine and other alkaloids in the smoke. The use of a cigaret holder, especially with fresh filters in the stem, and avoidance of burning too short a stump of cigarets, may diminish the physical and some of the chemical sources of irritation. Only relatively slight reduction in the nicotine content of the smoke is obtained by these means. Most of the so-called denicotinized cigarets contain little less nicotine than available oriental or Caribbean brands, but the recently introduced naturally low nicotine tobaccos substantially diminish this factor. So-called asthma cigarets, containing cubeb, stramonium, lobelia, potassium nitrate or other drugs, were formerly frequently used in treatment of attacks, and even tobacco has been recommended during attacks, but these are rarely recommended now.

COLD STERILIZATION OF INSTRUMENTS

To the Editor:—*What are the most reliable solutions for cold sterilization of instruments and hypodermic needles? How does 70 per cent ethyl alcohol compare with benzalkonium chloride 1:200 and with cresol solution?*

E. R. Kaback, M.D., Otisville, N. Y.

Answer.—Chemical agents cannot be relied on to sterilize instruments, syringes and needles, primarily because such agents do not destroy bacterial spores. Neither is virus of homologous serum jaundice always destroyed by chemical agents. Sterilization by heat is the only positive method; subsequent to heat sterilization, instruments may be stored in sterile solutions of certain chemical agents that contain rust-proof substances.

Price (*Arch. Surg.* 60:492 [March] 1950) stated: "For many reasons alcohol is an unsatisfactory agent with which to attempt cold sterilization of 'sharps' and other instruments. Spores are not killed. Even vegetative bacteria may escape destruction if they are hidden in the joint of scissors, or are protected by residual grease or blood clot or if they lie in some inaccessible part of a complex instrument, to which the alcohol does not penetrate. Alcohol, or any other cold solution for that matter, should not be expected to sterilize the lumen of a needle dropped into it. A momentary dip of an instrument into alcohol is a futile gesture; yet prolonged soaking tends to rust metal. No ideal germicidal solution for cold sterilization of instruments has yet been discovered. Some of the better preparations in current use contain alcohol as an ingredient."

TYPHUS IMMUNIZATION

To the Editor:—*I am planning to travel an irregular route through the Carribbean Islands, stopping in out-of-the-way hamlets. Should I have typhus immunization before I go?*

Darius Gray Ornston, M.D., Philadelphia.

Answer.—Although the danger does not seem to be great, it would be a good precaution to have typhus immunization before starting on your journey.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

BLACKSTRAP MOLASSES

To the Editor:—*I would appreciate information about the merits of blackstrap molasses.*

C. Ward Crampton, M.D., New York.

Answer.—The following information seems to be reliably established in regard to the nutritive value of blackstrap molasses.

The approximate composition is sucrose 36%, invert sugar 21%, ash 7 to 15%, and moisture 13%. (average of 100 samples from major sugar production areas, published in 1947). Ash has a potash content of about 50%, expressed as K_2O; lime 6.5%, expressed as CaO, and magnesium oxide 4.3%, expressed as MgO. The anions are chiefly sulfates and chlorides, with some carbonate, silica, and phosphate. The approximate vitamin content is, in milligrams per ounce of dry weight:

inositol	50.0
thiamine	0.024
riboflavin	0.069
pyridoxine	0.054
nicotinic acid	0.629
pantothenic acid	1.80
biotin	0.048
folic acid	0.00122

Note that in no instance, with the exception of inositol, does the vitamin content reach a value that makes an appreciable contribution to the human diet, when compared with other recognized protective foods. Despite the fact that molasses does contain a variety of minerals and vitamins, there is no justification for giving it major recognition as a protective or health food. It is widely known over the entire world as a stock food, and it is likely to remain in that category among informed persons.

ATHLETICS AND RHEUMATIC FEVER

To the Editor:—*At the age of 5 years, a boy had an acute attack of tonsillitis with fever and a secondary streptococcic infection of the blood stream. At this time, a mitral, presystolic murmur developed. This was before the days of antibiotic drugs. After months of complete bed rest, there was a seemingly complete recovery. After this episode a tonsillectomy was done. Joint symptoms were never pronounced. Now 10 years later, the patient presents no evidence of disease. May one call the disease described rheumatic fever? What advice should be given the parents regarding his participation in athletics?* *M. G. Seelig, M.D., Atherton, Calif.*

Answer.—From the history of acute tonsillitis occurring at the age of 5 years, with findings of mitral and presystolic murmur, one must conclude that the patient suffered from an attack of rheumatic fever with rheumatic heart disease. If at present the patient shows no evidence of disease, it would not seem necessary to advise his parents that his participation in athletics, such as baseball, football, basketball and tennis, need be restricted.

SPECIFIC GRAVITY OF URINE

To the Editor:—*What effect have glycosuria and albuminuria on the specific gravity of the urine? Will sugar or albumin of 1+, 2+, 3+, or 4+ raise the specific gravity appreciably?*

F. A. Stewart, M.D., Colorado Springs, Colo.

Answer.—Glycosuria and albuminuria increase the specific gravity of the urine. Roughly, each 1% of dextrose in urine will increase specific gravity by 0.004 and each 1% of protein by 0.003. If 4+ protein be taken as 500 mg. per 100 cc., the specific gravity increase due to albumin would be less than 0.002. If 4+ sugar be taken as 2%, the increase would be 0.008. Actually, terms like 1+ have no quantitative value and in different laboratories might be applied to urines differing twofold to fourfold in content of sugar or albumin. In the same laboratory, 4+ may be used for one specimen with 1.8% and for another with 12% sugar content, or for one specimen with 350 mg. and another with 5,000 mg. of albumin per 100 cc. The difference in specific gravity of the two former specimens would be 0.040; of the latter two, 0.014.

POOR OBSTETRICS

To the Editor:—*A multigravida ruptured membranes spontaneously three weeks prior to term; one week later she was admitted to the hospital for what was thought to be false labor. The attendant diagnosed a breech presentation and dismissed her from the hospital after contractions ceased. Four days later, a second attendant was called; a hand prolapsed from the vagina, and the transverse presentation was recognized. The patient was hospitalized, and a rectal examination was done. The attendant felt there was dilatation of about 4 cm. and gave 0.10 cc. of posterior pituitary and repeated this dose in 30 minutes. Only a few slight contractions resulted. A third attendant saw the patient and performed a podalic version under deep ether anesthesia. There was a contraction ring at the internal os, and an arm was delivered with difficulty, with fracture of the humerus. Difficulty was experienced in delivering the after-coming head with Piper forceps through a partially relaxed contraction ring. However, both mother and child were in good condition soon after delivery. Was the use of posterior pituitary judicious?*

M.D., Georgia.

Answer.—Not only the mother and baby but also some of the attendants were fortunate in this case. This represents poor obstetrics. It is extremely hazardous and a sign of complete ignorance to give a patient posterior pituitary in the presence of a transverse presentation, regardless of the amount of cervical dilatation. Luckily the posterior pituitary produced only "a few slight contractions." Furthermore, the contraction ring at the internal os was most likely not a contraction ring but simply an indication that the cervix was not completely dilated. This incomplete dilatation most likely accounted for the difficulty in performance of the version and also in delivery of the after-coming head with Piper forceps. One should never apply forceps before the cervix is completely dilated.

SYPHILITIC BLOOD AND TRANSFUSIONS

To the Editor:—*What is the consensus on the institutional use of syphilitic blood for transfusions (infectiousness, treatment of the blood and medicolegal aspects)?*

A. Gonzalez-Lujan, M.D., San Jose, Costa Rica, C. A.

This inquiry was referred to two authorities, whose respective replies follow.—Ed.

Answer.—It is generally accepted that Treponema pallidum in citrated blood dies after 48 to 96 hours of storage in the refrigerator. Some of the state departments of health in the United States prescribe that blood be kept at refrigerated temperature for two to four days before being used. According to current knowledge, therefore, citrated blood maintained for two to four days at refrigerated temperature is no longer capable of transmitting syphilis.

Answer.—The Bureau of Legal Medicine and Legislation has had a number of inquiries concerning this matter which indicated that there have been legal proceedings instituted against physicians who have given patients blood of a syphilitic donor, but apparently none of these cases have reached the appellate courts. They have either been settled or have terminated in trial courts. One case arose in Connecticut which reached the Supreme Court of Errors, but it was remanded to the trial courts for a new trial because of an error committed by the lower court with respect to the statute of limitations.

In the absence of an acute emergency, a physician who uses the untested blood of a donor for transfusion, and thereby transmits syphilis to the recipient, should be prepared, in case of suit, to justify his course of action by convincing evidence that in pursuing the course he did, he exercised that reasonable degree of skill, knowledge and diligence ordinarily possessed and exercised by physicians under the same or similar circumstances. In an acute emergency, a physician may be faced with the choice of using the blood of an untested donor, thereby assuming the risk of transmitting syphilis to his patient, or refusing to use the untested blood, thereby assuming the risk that his patient might die because of his refusal to use the blood. When he is faced with such a choice, the alternatives should be fully explained to the patient or to someone authorized to act for him or her, leaving the patient or other responsible person to exercise his or her own judgment in accepting or rejecting the blood of the untested donor. In such a case, the acceptance or rejection should by all means be in writing. When a patient cannot make a rational decision and when no other authorized person is available to act in his or her stead, and an emergency exists, it is difficult to conceive of a court's condemning a physician for adopting necessary procedures to save his patient's life. After all, syphilis is curable. A life extinct is beyond recall.

PENILE LESIONS THAT SIMULATE RINGWORM

To the Editor:—*A patient had a lesion on the glans penis, and the pathologist reported that fungi were present. At first the lesion was sharply circumscribed and flat, with loss of the normal texture of the glans; later there developed a scaling appearance, which looked more like fungus. He has no evidence of fungus infection elsewhere on the body. Please give advice regarding treatment. I have tried (1) ointment sopronol® propionate-caprylates compounds; (2) desenex® ointment, and (3) indelible pencil applied locally. At present half-strength Whitfield's ointment is being used. None of these has helped.* H. E. Rudersdorf, M.D., Sioux City, Iowa.

Answer.—Penile lesions that simulate ringworm are sometimes manifestations of diseases such as fixed drug eruption, psoriasis, lichen planus, or erythroplasia. If hyphae or spores were recovered from the lesion, it should respond to the type of treatment already used. It would be well to culture the organism and, if it is found that fungus is no longer present, to perform a biopsy. If fungus is present, the lesion might respond to treatment with carbol fuchsin or dilute, ⅛ strength, benzoic and salicylic acid (Whitfield's) ointment.

STIMULATION OF GRANULATION AND EPITHELIALIZATION

To the Editor:—*I have used Peruvian balsam for many years to stimulate granulation, and it has seemed to be effective. Is there some modern substance that has the same action? I have also used scarlet red to induce epithelialization, but it is not adherent to a moist surface. Is there a better substance that will stay more intimately applied?*

William H. Oatway Jr., M.D., La Vina, Calif.

Answer.—Among other substances used are chlorophyl compounds, red blood cell paste and acetic acid, 0.25 to 0.5 per cent mixed with 5 per cent glycerin and isotonic sodium chloride solution. Each of these has its advocates, as has Peruvian balsam. Healing of lesions may be delayed because of infection or other factors, such as poor circulation in the involved area. It is extremely doubtful that granulation and epithelialization can be stimulated in the sense that tissue repair is accelerated beyond the normal rate. Conceivably, certain of these agents may bring about a local condition more conducive to a normal healing process.

CORTISONE, HAY FEVER AND PREGNANCY

To the Editor:—*What is the status of orally administered cortisone in treatment of ragweed or other hay fever? Is there any danger in its use during any of the trimesters of pregnancy?*

M.D., Canada.

Answer.—The available evidence for the effectiveness of cortisone in hay fever is as follows: The results vary with different workers, but there is a rather general trend in the feeling that the benefit in hay fever is not as pronounced or as frequent as in asthma. On the question of the effect of cortisone given orally there is increasing evidence that the oral route is as useful as the subcutaneous. The doses of cortisone to be used in a condition such as hay fever would depress pituitary function. Since pituitary activity is an essential phase of the physiology of pregnancy it can be concluded that cortisone would be contraindicated in this state.

RECURRING GALLSTONES

To the Editor:—*A 42 year old man underwent a cholecystectomy for gallstones in May 1940. Common duct stones were removed in a second operation in 1948, at which time common duct T-tube drainage was employed for nine months, with normal cholangiograms. In January 1951, the common duct was found filled with soft stones and biliary mud and required long-armed T-tube drainage. Results of liver function tests have not been diagnostic of any malfunction of the liver. Please advise on what procedure should be done beyond prolonged drainage to obviate further recurrent deposits in the ducts.*

John C. Cottrell, M.D., Long Beach, Calif.

Answer.—No alteration in liver function has been demonstrated to accompany or precede the formation of stones in the gallbladder or biliary ducts. Furthermore, no alteration in the chemical composition of hepatic duct bile has been found to accompany or precede the formation or re-formation of stones in the biliary ducts. Theoretically an excessive amount of cholesterol in the bile or a diminished amount of bile salts and higher fatty acids, which keep the cholesterol in solution, should favor the formation of cholesterol stones; some evidence implicating both of these factors has been obtained. It seems likely that the great tendency for stone formation in the gallbladder as compared with the exceedingly rare formation of stones in the common duct is due to the concentrating function of the gallbladder mucosa and the resulting concentration of the gallbladder bile. It seems likely that in most cases gallstones form in the gallbladder and subsequently escape into the cystic, common and hepatic bile ducts. While there is considerable question that calculi form spontaneously in the bile ducts, there is no doubt that calculi, originating in the gallbladder and passing into the bile ducts, can increase markedly in size in the new location. In many cases, stasis of bile in the common bile duct brought about by the presence of stones is a factor in this growth of common duct calculi. Foreign bodies, such as rubber tubes, vitallium® tubes or glass cannulas, in the common bile duct or hepatic duct regularly cause the deposition of compounds of calcium and bile pigment. In the case described, it is probable that the common bile duct has become markedly enlarged as a result of the formation and re-formation of common duct stones and resultant biliary stasis. In cases of this type, excellent results have been obtained by anastomosis between the common bile duct and the duodenum after the stones in the duct have been removed. If such an anastomosis is made, it should be of good size, 1 to 2 cm. in length, so that duodenal content, passing into the common bile duct during digestion, may readily escape later into the duodenum. Whereas a large anastomosis usually provides complete relief, a small anastomosis may do more harm than good.

ALCOHOL AND GOUT

To the Editor:—*Why are alcoholic beverages not permitted for a patient having gout? All of my textbooks recommend omission of alcoholic beverages, but no reasons are given.*

T. E. Kilkenny, M.D., Winneconne, Wis.

Answer.—There have been divergent opinions as to the importance of alcoholic beverages in the treatment of gout, but clinicians of wide experience have repeatedly observed provocation of acute attacks of gout after alcoholic sprees.

Disturbances of uric acid elimination have been observed in healthy subjects following administration of alcoholic liquors; also, mobilization of stored purine has been noted in gouty patients following the use of alcohol (Grafe, E.: Metabolic Diseases and Their Treatment, Philadelphia, Lea & Febiger, 1933, p. 481). This evidence suggests, but does not prove, that the metabolism of gouty patients might be disturbed by alcohol.

As regards most alcoholic liquors, purine content is negligible. However, dark beers have a purine content of 0.01 to 0.02 per cent, and, if such beers are consumed in large quantities, the amount of purine added to the intake would be important.

BORIC ACID A POOR DEODORANT

To the Editor:—*I would like information regarding the use of boric acid powder as a body deodorant with respect to its efficacy and its hazards.*

Watson W. Eldridge, M.D., Washington, D. C.

Answer.—No carefully controlled studies of the effect of boric acid as a deodorant have been found. Boric acid will not penetrate the unbroken skin. Long immersion of the extremities in saturated (5 per cent) solutions fail to show any increase of boron in body fluids or excretions. However, it is rapidly absorbed through abraded skin or granulating wounds and under these circumstances is capable of producing marked toxic symptoms.

Boric acid is a very feeble bactericidal or bacteriostatic agent. Since its effectiveness as a deodorant would depend on its ability to decrease the number and type of the skin surface flora, it is probably a poor choice for deodorant purposes.

DAILY WETTING OF HAIR

To the Editor:—*Is there any harm in thoroughly wetting the hair daily, for cosmetic reasons? I have done it for years and have all my hair. Many who disclaim the practice are bald.*

M.D., New York.

Answer.—There is no harm in wetting the hair daily. It is entitled to the same care that one gives the face. A wet scalp, however, is prone to attract dirt.

CONGENITAL SYPHILIS

To the Editor:—*On page 77 of the May 5, 1951, issue of* The Journal *is a question and answer regarding congenital syphilis. The answer is completely in error. The doubtful cord serologic test is almost certainly due to transfer of maternal reagin. A saddle nose in a newborn infant is of no significance —they all have saddle noses. Under no circumstances should this infant have been treated for congenital syphilis until the diagnosis was established by the appropriate measures, which are outlined in any standard text on syphilology.*

J. E. Moore, M.D.,
803-807 Medical Arts Bldg.,
Baltimore 1.

To the Editor:—*I do not fully agree with the answer to the query on "Congenital Syphilis" in* The Journal, *May 5, 1951. The infant may or may not have congenital syphilis, but certainly that diagnosis cannot be assumed in the absence of clinical manifestations and equivocal cord serologies. A single positive cord serology cannot be accepted either as final elimination or confirmation of infantile syphilis. If a steadily rising titer in quantitative Kahn tests is found on weekly or semimonthly examinations for three months in the absence of clinical manifestations, then the infant probably has congenital syphilis and treatment can be given. Also, if x-ray of the long bones reveals osteochondritis, then the infant probably has syphilis.*

J. M. Greenhouse, M.D.,
206 Metropolitan Bldg.,
435 Missouri Ave.,
East St. Louis, Ill.

To the Editor:—*In Queries and Minor Notes in* The Journal *of May 5, 1951, is a letter requesting advice on the management of an infant born of a treated syphilitic mother. The consultant's opinion that the baby is "probably syphilitic" and should be immediately treated with penicillin is erroneous. It is now recognized that many nonsyphilitic infants born of syphilitic mothers are seropositive at birth and become seronegative in the course of the first few months of life. In the absence of clearcut clinical or roentgenologic evidence of syphilis, the diagnosis must not be made purely on serologic grounds under the age of 3 months. Since the mother in question had received treatment and was seronegative and the cord blood showed only a minimal amount of reagin, it is highly probable that this infant does not have congenital syphilis.*

The proper course would be to examine this baby clinically and serologically at intervals of two to three weeks and to x-ray the long bones in search of evidence of syphilitic osseous disease. Should the clinical and roentgenographic examinations remain negative and should the serologic test change to negative in the absence of antisyphilitic treatment, congenital syphilis could be excluded in this child by the age of 4 months.

Ira Leo Schamberg, M.D.,
2031 Pine St., Philadelphia 3.

To the Editor:—*I disagree with the answer to the query on "Congenital Syphilis" in* The Journal, *May 5, 1951. The flat statement that a newborn infant with a positive cord serologic test for syphilis (and in this case the result was doubtful), born of a mother who presumably has inadequately treated latent syphilis, "probably" has syphilis is absolutely incorrect. It has been proved that maternal syphilitic reagin may appear in the blood of nonsyphilitic infants for varying periods after birth and that the results of the cord serologic test are of little importance. When positive, the test may be merely evidence of maternal rather than infant infection. The serologic test on cord blood is worthless as a working diagnostic tool, because in a child with a negative cord reaction to a serologic test for syphilis the signs of congenital syphilis may ultimately develop, and a child with a positive cord reaction may ultimately prove to be nonsyphilitic. Furthermore, once treatment for congenital syphilis has been given, the child must be considered as having had congenital syphilis for the rest of his life, even if the diagnosis might have been in error. In an apparently normal, healthy infant, there is no need to rush into therapy, as was advised, until the diagnosis is definitely established.*

Definitive diagnosis can be aided by the use of serial roentgenograms of the long bones, although, owing to artifacts and misinterpretations, these studies can be considered as only about 25% accurate. However, serologic tests for syphilis done weekly in a serial manner on the infant's blood can give an accurate estimation of the infant's syphilitic status. The quantitative titer of the infant's blood is usually equal to, or lower than, the titer of the maternal blood, and the titer subsequently falls and the reagin finally and permanently disappears in the first few weeks of life. In such infants, subsequently observed, other evidence of congenital syphilis does not develop, thus demonstrating the maternal origin of the reagin, which usually disappears in the first month of life. If by the twelfth week one finds increasing amounts of reagin in the infant's blood, the child can be considered as syphilitic. The presence of reagin, therefore, at the end of the third month is indubitable evidence that the child is syphilitic.

The presence of reagin of maternal origin in an infant's blood is more readily detected by a complement-fixation test than by a flocculation test, and for this reason the routine use of the flocculation test is recommended in infants suspected of having circulating maternal reagin rather than congenital syphilis. Associated with increasing amounts of reagin in the circulating blood of the congenital syphilitic child is the usual development of definite clinical signs of syphilis, such as dark field positive cutaneous lesions, bullae, snuffles, and periosteal bone lesions.

In regard to the mother, although the basis on which the diagnosis of syphilis was originally made is not stated, we must consider her as having syphilis, since treatment was instituted and was inadequate. Certainly, an examination of the cerebrospinal fluid is indicated in the immediate future, before or at least in the first week of therapy, and repeated a year later. The total penicillin dosage as given (6,000,000 units) is adequate for early and latent syphilis, but, assuredly, around 10,000,000 units should be given for central nervous system syphilis, and a cerebrospinal fluid examination is indicated to determine whether central nervous system syphilis exists. It should never be presumed that a negative blood serologic reaction means that the spinal fluid is normal.

TREATMENT OF COMPOUND FRACTURES IN THIS ANTIBIOTIC AGE

J. Albert Key, M.D., St. Louis

Since one of the chief objectives in the treatment of compound fractures is to prevent or combat infection in the wound, and since the introduction of antibiotics has profoundly influenced treatment of infections in general and of the pyogenic infections in particular, it seems in order to review the treatment of compound fractures in the light of the present day knowledge of antibiotics and the facility with which these potent agents can be used. In connection with some other work, I recently sent a questionnaire to a group of 24 orthopedic surgeons, in which I inquired about their use of antibiotics and other measures in the treatment of compound fractures. I found that there are wide differences of opinion concerning the dosage of antibiotics as well as minor differences on other phases of the treatment of these injuries.

Since compound fractures are among the most frequent and important injuries that man is heir to in time of peace as well as in time of war, it is evident that an effort should be made to standardize the treatment of these grave injuries. However, not only is there considerable variation in the character and severity of the lesions present and in the degree of contamination of the wound, but there is also considerable variation in the conditions under which the wound will be treated and in the capability of the surgeon who is to administer the treatment. Consequently, it is hardly possible to standardize the treatment of these injuries, but it is possible to present a method of treatment that is reasonably elastic and thus capable of modification in the hands of the individual surgeon and yet to offer a procedure that will yield a satisfactory result in a high percentage of the cases. This paper is an attempt to present such a method.

EMERGENCY TREATMENT

A compound fracture is nearly always a serious injury and will necessitate surgical treatment. In most instances the patient should be admitted to the hospital if one is available within a reasonable distance from the site of the accident and if transportation to the hospital is possible. At the site of the accident the treatment will vary with the severity of the wound and the condition of the patient. The injury may vary from a laceration with fracture of the terminal phalanx of a finger or toe to an injury of the utmost gravity, in which the patient is either killed outright or in which his life is in imminent danger. At the site of the injury the extremity should be straightened and gross deformities reduced by manual traction, and this traction may be continued until a temporary splint has been applied. The wound should be covered with a clean dressing. If possible, this should be a sterile dressing. If such is not available, a clean piece of cloth may be applied to the wound and bound on with a suitable bandage. If hemorrhage is present and of sufficient degree to demand attention, efforts should be made to control the hemorrhage either by means of a pressure dressing or of a tourniquet. If necessary, a tourniquet can be improvised. If sulfonamide powder is available, this may be sprinkled in the wound before the dressing is applied.

The question then arises as to whether or not the fracture should be splinted by rigid external fixation on the spot, and there are many surgeons who believe that the old dictum "splint them where they lie" should be applied to the treatment of every compound fracture, regardless of the gravity of the wound or of the distance over which the patient must be transported before he reaches a hospital where definitive treatment can be administered. Common sense should determine the cases in which splinting should be done before the patients are moved from the scene of the accident. In civilian life most injuries occur in situations in which the patient can be taken to a hospital and in which the journey will require less than one hour; consequently, it is not necessary to apply rigid splints to every compound fracture. Such splints need be applied in only those cases in which transportation without splinting will be very painful or increase the damage to the soft tissues and thus promote shock and hemorrhage. This applies especially to fractures of the femur and of both bones of the leg and to severe fractures and fracture dislocations at the ankle and of the arm or forearm. In some instances a fractured upper extremity can be supported on a pillow or the arm and forearm can be bound to the chest, and a fractured lower extremity can be bound to the opposite lower extremity if necessary. Likewise, all patients with frac-

Read at the Fourth Clinical Session of the American Medical Association, Cleveland, December 8, 1950.

tures, except the severe ones mentioned above, can usually be transported with relative safety in an automobile. Persons with major fractures of the lower extremity should be permitted to lie where they are until an ambulance can be sent for and they can be transported in a recumbent position. In case of doubt, splints should be applied and an ambulance should be used.

Usually it is not necessary to give any antibiotics at the site of the accident because this type of treatment is better given at the hospital, where a record will be kept of the drugs that have been administered. On the other hand, if it is known that considerable time will elapse before definitive treatment is instituted, it is well to give a severely injured patient a single large dose of penicillin —not less than 100,000 units and, preferably, 400,000 units, of penicillin G procaine fortified.[1] The same policy should be followed for sedation. If the patient is suffering a great deal of pain and morphine or another sedative is available, it should be given in a dose sufficient to make the patient relatively comfortable. This not only will relieve pain but will also tend to lessen shock. Some object to morphine in the presence of brain injury, but it may do more good than harm.

TRANSPORTATION

The patient should be taken as soon as possible to a hospital where expert treatment is available and will be given. As stated above, he should be transported in an ambulance if he is suffering from a major fracture of the lower extremity. Otherwise, he can usually be moved more expeditiously in an automobile. He need not be taken at breakneck speed, as minutes are less important than is avoidance of roughness in transport and in handling the limb.

ADMISSION TO THE HOSPITAL

The patient should be admitted to the hospital as an emergency case with as little "red tape" as possible. He should not be taken to the x-ray room immediately, but should be left in the emergency room or put in a comfortable bed and examined by a competent surgeon who has had sufficient experience and judgment to enable him to evaluate other injuries, such as those to the head, chest, and abdominal and pelvic viscera, and the general condition of the patient. If the patient is in a condition of surgical shock or if shock is impending, this is the major consideration and efforts should be made immediately to combat the shock with the usual measures: elevation of the foot of the bed, rest, application of external heat, and replacement of blood by plasma or fluids and then whole blood, as necessary. If he has lost much blood, it should be replaced as soon as possible. Also, he should be relieved of pain. If his wound is not properly dressed, a proper dressing should be applied, and, if indicated, the fracture should be immobilized either by traction or by a splint. Oxygen may be administered if it is indicated. If hemorrhage is present, it should be arrested by suitable means—tourniquet, clamp or pressure dressing. The patient should be kept warm, quiet and comfortable while in shock. He should be given a large dose of penicillin as soon after admission as possible if it has not been administered elsewhere.

If the wound is covered by a satisfactory dressing, it should not be disturbed until the patient is in the operating room and ready for definitive treatment. An effort should be made to determine all injuries present as well as the time that has elapsed since the injury occurred; the time should be recorded because in a case of compound fracture the number of hours elapsed between the injury and the operation is an important factor in determining the method of procedure. If the patient is not in a condition of shock, he should be taken to the x-ray room as soon as an adequate history and physical examination have been completed. The blood count and typing for transfusion, if the patient is sufficiently injured to warrant this, should be done as part of the physical examination. Unless the fracture is suitably splinted, splints should be applied before the patient is sent to the x-ray room, since the usual x-ray technician is not qualified to manipulate an extremity in which there is a fresh fracture unless it is adequately splinted.

PREOPERATIVE TREATMENT

It is well to give a dose of morphine or other sedative as soon after the patient has been admitted as possible if this has not been done previously and is indicated. Likewise, the patient may be given 100,000 to 400,000 units of penicillin and 3,000 units of tetanus antitoxin or a booster dose of 1 cc. of tetanus toxoid if he has been immunized. These should be given and recorded if they were not given before admission.

He should be taken to the operating room as soon as is practicable. A few minutes are not important, but hours may be; this is especially true if six hours or more has elapsed since the time of the injury and the patient's admission to the hospital. If shock is present, x-rays may be made while the patients is in bed after he has begun to react from the shock, or they may be made in the operating room after the patient is on the operating table.

TREATMENT IN THE OPERATING ROOM

The patient should be placed upon either a regular operating table or a fracture table before the dressings and splints are removed. If the fracture involves the femur or both bones of the leg, it is especially desirable that he be placed on a fracture table and that traction be applied to the extremity in order that it may be supported in a position suitable both for operation and for the application of a plaster cast after the operation is finished.

Administration of the anesthetic is usually begun before the operative field is prepared. My associates and I usually use general anesthesia, but local, regional or spinal anesthesia may be used by those who are especially equipped to do so and are skilful in the use of these methods. A severely injured patient may be given plasma or blood before, during and after the operation as indicated by his general condition.

After the patient has been anesthetized, the dressings are removed, the extremity is placed in a suitable position for the operation, and the surrounding skin over a sufficiently wide area is scrubbed with soap and water (we now use one of the new antiseptic soaps, septisol®

---

[1] Each cc. of penicillin G procaine fortified contains 300,000 units of procaine penicillin G and 100,000 units of potassium penicillin G crystalline with 2% aluminum stearate w/v in sesame oil.

or pHisoderm,® which contain solution G 11 [hexacloro-phene]). The skin is then shaved, and the scrubbing is continued until it is clean. It is then rinsed with sterile water or salt solution and wiped dry, then washed with ether, and iodine tincture or some other skin antiseptic is applied. During the preparation of the skin, the wound is covered with a sterile dressing and the washing and shaving are extended up to the edge of the wound. The wound may then be flushed with isotonic sodium chloride solution before the skin is dried and the skin antiseptic is applied. If the skin preparation has been done by the surgeon, he should now change his gown and gloves. The field is then draped and the operation of débridement of the wound and reduction of the fracture is performed. If the circulation distal to the fracture is adequate, an effort should be made to save the extremity.

DÉBRIDEMENT

The operation of débridement has as its objective the removal of devitalized and contaminated tissue and foreign material from the wound in order that it may heal without becoming infected. The manner in which it is performed varies considerably in different clinics. One surgeon may open the wound widely and remove little or no tissue, while another may perform a wide block excision of the wound, and there are all variations between these extremes. We believe in a conservative débridement, in which the margins and contaminated surfaces of the wound are excised and foreign material is removed. The wound is débrided in layers, but this is done with the sacrifice of as little viable tissue as possible. This requires a careful excision of the wound, layer by layer, care being taken not to force contaminated tissue into the depths of the wound by injudicious retraction or exploration. These statements do not apply to wounds that are more than 24 hours old, have not been adequately protected by sulfonamides or penicillin and are infected. These wounds are opened and washed thoroughly; necrotic material and foreign bodies are removed, and the wounds are then packed loosely with petrolatum gauze, and no effort is made to excise their infected surfaces.

In dealing with through-and-through wounds such as those caused by shell fragments or other missiles, both the wound of entrance and the wound of exit are débrided, the latter necessitating the more extensive operation. An exception is a compound fracture caused by a high velocity missile such as a rifle or machine-gun bullet. These wounds tend to be relatively sterile, and débridement is not necessary. The skin edges may be excised and the skin sutured, or the wounds may be painted with a skin antiseptic and covered with a sterile dressing and the fracture treated as a simple fracture, except that penicillin is given as in the postoperative care of compound fractures. In case of multiple wounds only the major ones are débrided.

The operation of débridement is performed either with or without a tourniquet, depending upon the location of the injury, the condition of the patient and of the extremity and the wishes of the surgeon. We usually use a pneumatic tourniquet, and this is released when the operation is finished and before the wound is closed or the pressure dressing is applied. Early in the operation the wound is inspected and material for culture obtained, usually with a cotton swab, from the depths of the wound; or some bits of devitalized tissue, especially muscle, are excised and implanted in suitable mediums. These cultures are especially valuable for the early detection of gas bacillus contamination and for determination of the penicillin resistance of bacteria in the wound.

The margins of the wound are excised, with removal of as little living skin as possible, usually a thin strip about ⅛ in. (0.3 cm.) wide entirely around the wound. Large, loose flaps of skin are saved when possible. However, skin should be excised if it has been subjected to crushing and is consequently thinned and obviously devitalized as well as soiled by dirt that has been ground into it. Although it is important to conserve as much skin as possible, it is not advisable to save skin that is dead and will slough and become infected. The knife and forceps that have been used in excising the margins of the wound are discarded.

The wound is then enlarged, usually by vertical incisions both upward and downward in such a manner that the edges can be retracted and the depths of the wound inspected. As the wound is inspected, any gross foreign bodies that are seen are removed. Blood vessels that are bleeding or that may bleed later are clamped and tied with fine absorbable surgical suture or silk as they are encountered. The wound is then irrigated gently with isotonic sodium chloride or sulfonamide solution and the subcutaneous and deeper tissues are débrided by excision of a thin layer of the surfaces of those tissues which were exposed in the wound. When dirt or other foreign material is embedded in the tissues, especially the loose areolar tissues, excision is preferable to an attempt to pick out the foreign material. Devitalized muscle is removed. This is muscle that is crushed, has lost its structure, is swollen, and does not bleed or retract when cut. On the other hand, much contused but viable muscle may be present in severe compound fracture wounds, and this muscle may be dark in color and swollen without being devitalized; usually this muscle should be allowed to remain. It is important to avoid removal of muscle that can be expected to live and resume its function. On the other hand, masses of dead muscle left in a wound will almost always lead to infection, and this cannot be prevented by the use of antibiotics. The débridement is as atraumatic and conservative as is consistent with a satisfactory operation.

If a joint cavity communicates with the wound, the margins of the capsule and synovial membrane extending around the wound and into the joint are excised, the cavity is thoroughly irrigated and inspected and foreign particles or loose pieces of bone or cartilage are removed. Contused or soiled cartilage is excised. If necessary, the opening into the joint is enlarged to permit inspection of the cavity. After it has been débrided and thoroughly irrigated, the joint cavity may be closed loosely, either with or without drainage.

The bone is now inspected, and completely loose fragments of bone are removed, although very rarely a single large fragment that is loose may be washed off and replaced for use as a graft or internal splint in order to preserve continuity and length of the shaft. All fragments of bone that are sufficiently attached to soft tissues to have a reasonable chance of surviving are left in the wound unless they are grossly soiled. The ends of the fragments are not removed unless they are grossly contaminated by dirt or other foreign material. If such material is ground into the bone or forced into the medullary canal, the ends of the fragments must be excised until only clean bone is left. When this is done, it is usually advisable to shape the ends of the fragments so that the fracture will be relatively stable when it is reduced and immobilized in a cast.

An exception to the above is in epiphyseal separations in which the end of the shaft has been forced into the dirt. We have hesitated to excise the end of the shaft for fear of interfering with growth; consequently, the epiphyseal end is scrubbed thoroughly with soap and water, usually by means of a sterile brush, then irrigated and replaced in the wound, only small portions that still contain dirt being excised with rongeur forceps.

The wound is again inspected, and a further search is made for any remaining foreign material or devitalized tissue in the wound. But the tissues are not widely opened in order to search for deeply buried missiles. These can be removed later if necessary. The ends of tendons and nerves that have been cut or torn are excised by a clean transverse section, and these tendons and nerves are then repaired, usually with fine silk if the condition of the wound and the patient permit. If for any reason haste is imperative, they may be simply tied together with fine silk or, preferably, with a stainless steel wire suture. The bodies of cut or torn muscles are united by widely spaced mattress sutures pulled just tight enough to coapt the ends, care being taken that all devitalized muscle is removed before the sutures are placed.

Reduction and Fixation of the Fracture.—The débridement and repairs having been completed, the displacement of the fragments is reduced as accurately as possible by traction and manipulation, and a decision is made as to whether or not internal fixation should be used. Since the advent of antibiotics and noncorrosive metals, internal fixation of compound fractures has been used with considerable success in a large number of cases. It offers the advantage of more complete immobilization of the fragments; this lessens the danger of postoperative trauma and of the development of dead spaces in the wound and thus lessens the danger of infection. On the other hand, the application of internal fixation, especially of screws, plates and medullary nails, adds to the trauma to the bone and further impairs the circulation of the bone. The same is true, to a lesser extent, of wires.

If internal fixation is not vitally needed, it should not be used. However, in fractures in which internal fixation will be of great advantage it may be used, and this is especially true in relatively fresh compound fractures that have been satisfactorily débrided and can be cared for by the surgeon after the operation. In fact we much prefer this to external skeletal fixation with multiple pins and, usually, to treatment by skeletal traction, as it saves time in the hospital.

A substitute for internal fixation is external skeletal fixation. This is provided by two Steinmann pins, one in the proximal and one in the distal fragment. These pins are applied after the operation is completed but usually before the wound is closed. It is advisable not to place them in the operative wound, but to insert them through intact skin and soft tissues. If reduction of the fracture is maintained until the cast is applied, these pins will usually insure that the fragments will not slip in the cast and they will always prevent shortening in the cast. The wound is again inspected and irrigated, not copiously but adequately, any further devitalized tissue is excised, and any further foreign material that can be identified is removed. For this final irrigation we use a saturated solution of sulfanilamide. The tourniquet is now removed, and any bleeding vessels that have been overlooked are ligated.

Closure of the Wound.—The next question is whether or not this wound should be closed. This will depend upon (1) the time that has elapsed since the accident, (2) the degree of soft tissue damage, (3) the amount and character of the soiling of the wound, (4) the ability of the surgeon to perform a satisfactory débridement, (5) whether or not it is possible to close the wound without too great tension, and (6) the postoperative care that the patient will receive. The decision is based upon the surgeon's experience and judgment, and it may be a very delicate one. We have successfully closed several wounds more than 24 hours old but do not advise this as a routine procedure even when the patient has received antibiotic therapy from the time of the accident.

In civilian life most compound fractures can be closed because they are seen relatively soon after the accident, the surgeon can keep in close contact with the patient after the operation, and it is not necessary that the patient be transported to another hospital after the operation.

In military life, and especially in war and under campaign conditions in which the skin is apt to be dirty before the injury is received and foreign material is apt to be carried deep into the tissues by the missile in shell or bomb injuries—especially when the patient is likely to be moved to another installation and cared for by another surgeon after the operation—the wound should be left open and closure attempted later by primary delayed or secondary closure.

If the wound is to be closed, the skin and subcutaneous tissues are approximated with a single layer of rather widely spaced sutures of chromicized absorbable surgical suture, silk or silkworm gut, depending on the choice of the surgeon. If such tension is present, this may be relieved by lateral incisions on either side of the extremity, thus permitting the skin to slide toward the wound, and, if necessary, these incisions may continue down through the subcutaneous tissue and even the deep fascia, and the defects may be covered with petrolatum gauze and permitted to heal by granulation, or a split thickness skin graft may be applied immediately. After the wound is closed, 100,000 units of penicillin is injected into the depths of the wound or into the joint if it is involved.

In some instances it is necessary to swing a flap of skin and subcutaneous tissue across the wound. When this is done, it is important that the flap have a sufficiently wide base and that it be sutured in position without tension and without constriction of the base, otherwise, it may slough and further complicate the condition of the patient. A definite effort should be made to cover nerves, tendons, and bones that are exposed in the wound.

In many instances, and especially in those in which, after débridement, there is a dead space or in which there has been extensive damage to the soft tissues, it is advisable to drain the wound for at least 48 hours. This is accomplished by a stab wound in the dependent portion of the wound. This stab wound is made sufficiently large so that a soft rubber tube or tissue, or a petrolatum gauze drain of adequate size can be passed through it to conduct fluid from the depths of the wound to the dependent surface of the extremity. Do not use through-and-through drains. In a wound involving a joint the synovial membrane can be closed loosely and the drain carried down to the membrane, or the end of the drain may enter the joint cavity, but drains should not pass through the cavity. If the wound is to be closed, the joint capsule and any ligaments that are cut or torn should be repaired. The drain should usually be removed in 48 hours and this removal can be accomplished through a small window in the cast.

If the wound is to be left open, it is packed loosely with gauze impregnated with petrolatum or preferably with fine mesh gauze impregnated with glycerin. The packing must be loose, otherwise it may act as a plug in the wound and promote infection. A pressure dressing is then applied. Pressure dressings are also used for the wounds that are closed but are especially desirable in those which are not closed. It consists of a mass of cotton waste or fluffed gauze (or, if this is not available, a rather heavy dressing of ordinary surgical gauze or cotton) that is bound onto the extremity with a gauze or woven elastic cotton (Ace® or tensor) bandage. Care is taken not to apply the bandage too tightly because it is important not to interfere with the circulation of the distal portion of the extremity. On the other hand, it should be tight enough to exert definite pressure and thus tend to prevent postoperative edema of the tissues as well as the accumulation of fluid beneath the skin. The extremity should be inspected at intervals, and, if at any time the circulation appears inadequate, the cast should be bivalved and the dressing loosened or split. It is our custom to use the pressure dressing whether the wound is left open or closed, and in case of doubt we are disposed to leave the wound open and to close it at a later time by either a primary delayed or a secondary suture, if possible. If this is not feasible, we may use skin grafts to cover the denuded area or may let the wound heal by granulation.

External Fixation.—After the pressure dressing has been applied, the extremity is immobilized in a splint with or without traction or in a plaster cast. In major fractures of the lower extremity that are to be immobilized in a splint with traction, the limb is supported on a Thomas knee splint or on one of another type, and skeletal traction is applied by means of a wire that is drilled through a suitable portion of the femur, tibia or os calcis. When traction is used on compound fractures in which the muscle has been severely damaged or destroyed, it is well to remember that considerably less weight is necessary than for a similar limb in which the muscles are intact; otherwise, serious distraction with delayed union or none may occur.

Most compound fractures are immobilized in plaster of Paris casts. When a cast is to be used, the pressure dressing and the extremity are wrapped in a layer of sheet cotton and the whole covered by the plaster bandage. Unpadded casts are dangerous in these injuries and are to be used only by those who are expert in this form of treatment. Care is taken to avoid displacement of the fragments during the application of the cast. The cast should be adequate for fixation of the part: a shoulder spica for injuries of the elbow, arm or shoulder and a hip spica for injuries of the hip, femur or knee. A plaster cast may also be used in the convalescent care of fractures that were treated by traction until the fragments began to unite. If necessary, one or more windows may be cut in the cast in order to permit dressing the wound.

Primary Delayed Suture.—Those wounds which are left open after débridement, but which are relatively clean, can in most instances be closed within from four to 10 days after the original débridement by a primary delayed suture. This is a simple closure of the wound without excision or undermining of the skin margins or excision of the surface of the wound. It is important that the wound be either sutured or covered with a skin flap or graft as soon as possible after the injury, as the successful closure of the wound converts the lesion into a simple fracture and this greatly simplifies the treatment.

Both primary delayed and secondary sutures are now performed without bacteriological control. It has been found that, with the aid of antibiotics, wounds that present a satisfactory appearance when the dressing is removed can be closed with relative safety. If, when the dressing is removed, bits of necrotic tendon, fascia or other tissue are found in the wound, these can be excised and the wound washed out, and if the latter looks clean it can then be closed with relative safety by simple interrupted sutures that draw the skin together. If this cannot be done without so much tension that the circulation is interfered with, it may be possible to close the wound by a plastic procedure (by sliding or shifting flaps of skin and subcutaneous tissue or by doing a split-skin graft). Tendons, nerves and bone should be covered if possible. When plastic procedures are used, denuded areas may be covered with a split-skin graft, and from that time on the injury is treated as a compound fracture that has been closed at the time of débridement. In many instances it is possible and wise to do the primary delayed suture through a window in the cast, thus avoiding the danger of displacing the fragments, and the same is true of secondary suture, though this is a more extensive procedure and may require a larger window.

Secondary Suture.—If for any reason the wound cannot practicably be closed by primary or primary delayed suture, it may be permitted to heal by granulation or be closed by secondary suture. The secondary suture is a more extensive procedure than the primary delayed suture because it is frequently necessary to excise not only the margins of the skin that have begun to grow over the wound, but also the surface of the wound itself and to undermine the skin edges in order to bring them together. Since more time has elapsed since the original injury, there is not so much danger of displacement of the fragments in a secondary wound closure as there is in a primary delayed suture. After the secondary suture the wound is immobilized in a plaster cast and treated as though it were a simple fracture. If the position of the fragments is not satisfactory, it can be corrected at the time of the primary delayed or secondary suture.

Postoperative Treatment.—If the patient has not received adequate protection from tetanus before the operation this should be attended to as soon as is practicable after the operation. The chemotherapy usually begun before the operation is continued afterward as long as necessary. We usually give a single dose of 300,000 units of penicillin G procaine or a fortified dose containing 100,000 units of soluble penicillin and 300,000 units of penicillin G procaine daily after the operation. In very severe cases in which there is unusual risk of infection this dose may be doubled, or, if the surgeon prefers, the patient may be given 100,000 units of soluble penicillin intramuscularly every two or three hours for the first few days until the danger of invasive infection is passed, then the dose can be decreased. This procedure is continued until the temperature has been normal for five to seven days.

As a rule we do not use any of the other antibiotics, i. e., aureomycin, terramycin, streptomycin, and chloramphenicol (chloromycetin®), unless it is found that the organisms that contaminate the wound are resistant to penicillin and unless gram-negative bacteria have been detected in the wound or the patient is not doing well on the penicillin. In that case we may shift to one of the other antibiotics or continue with the penicillin accompanied with the other drug. There are now available vials containing 300,000 units of penicillin G procaine, 100,000 units of buffered penicillin G, and 1 gm. of dihydrostreptomycin, all of which can be administered in a single 3-cc. aqueous injection. It is possible that the use of combinations of penicillin with one or more of the other antibiotics for the prevention of infections in compound fractures will be routine in the future. At present we use only the penicillin unless there is a specific indication for the use of some other antibiotic.

If the patient is in shock, this condition should be treated with the usual methods, special attention being paid to restoration of the blood volume. If the patient is anemic, he should be given transfusions until his red blood cell count has reached an approximately normal status. He should also be put on a high-protein diet. If the patient complains of excessive pain, if the pulse rate is unduly accelerated or the temperature is unduly elevated, the cast should be bivalved or a window cut to expose the wound, which should be opened, or the packing removed, if necessary, to permit adequate drainage. If gas bacillus infection occurs, appropriate surgical treatment should be instituted as soon as possible. If the circulation in the extremity is insufficient on account of traumatic vascular spasm, an effort should be made to relieve this condition by blocking the lumbar sympathetic chain with procaine hydrochloride (novocaine®).

The postoperative care of the fracture is similar to that of a simple fracture of the same type, except that in a compound fracture the bones may heal somewhat more slowly than in a simple fracture. If further surgery in the wound is indicated, whether for the purpose of restoring continuity of nerves or tendons, for plastic procedures on the skin or soft tissue or for procedures on the bone, it can now be done as soon after the injury as the healing of the wound will permit and one no longer has to wait for a period of many months for the disappearance of any latent infection in the wound, because this condition can usually be controlled with antibiotics. Restoration of function in these patients is carried out along lines similar to those used in the treatment of simple fractures, except that in compound fractures the immobilization may have to be continued for a longer time and there may be soft tissue injuries that add to the disability.

It is thus evident that the advent and general availability of potent antibiotics have improved the results but have not greatly altered the treatment of compound fractures. These injuries must still be treated promptly, and shock must be combated, as in the past. Likewise, the wounds must be débrided carefully, and, if they are closed by primary suture, it must be effected without excessive tension, and they must be watched carefully afterwards.

With the aid of antibiotics we are permitted a little more leeway as regards the elapsed time during which a given wound may be closed and are able to use internal fixation more freely than in the past. The principal benefit that can be attributed to these agents is the ability of the surgeon to perform immediate closure or primary delayed suture on most wounds and to cover others with split-skin grafts and thus obtain prompt healing of many wounds that in the past would have been doomed to months of chronic infection with resultant loss of function of the part. It is to be noted, however, that the antibiotics do not perform miracles in compound fractures and that the successful treatment of these injuries demands the same high degree of surgical judgment and skill that it did before these agents were available.

4952 Maryland Avenue.

Neutromuscular Transmission.—The general acceptance of the acetylcholine theory in neuromuscular transmission is based not only on the overwhelmingly positive evidence, such as, for instance, that acetylcholine is released on motor-nerve stimulation, that injections of acetylcholine can imitate all details of motor-nerve stimulation, and that there is at the neuromuscular junction a concentration of the enzymes which synthesize and destroy acetylcholine; but also on what I may call the negative evidence—that is, whenever the possibility existed to try out whether the nerve impulse could cause contraction without acetylcholine the answer was no, the nerve impulse was unable to do so.—W. Feldberg, M.D., The Physiology of Neuromuscular Transmission and Neuromuscular Block, *British Medical Journal*, May 5, 1951.

ACCELERATION OF CONVALESCENT CARE OF POLIOMYELITIS PATIENTS

Charles L. Lowman, M.D., Los Angeles

In the convalescent phase of poliomyelitis, the problem of delay in definitive treatment with its resultant personal and economic hardship must be faced. Early in the course of each case, the paralytic patient and his parents should be given comprehensive understanding of the aims and sequence of treatment and the need for establishment of a streamlined tentative over-all care program. This will not only increase the patient's understanding of the problems ahead but, if sincere effort is made to shorten convalescence, will also save him time and money.

The tendency has been great to follow the old teaching that continuous muscle reeducation should invariably be continued over a period of one to two years even though the need for early surgical intervention is clearly indicated. Parents naturally wish to avoid surgery, and sometimes it is possible to continue muscle training for a considerable period with a chance of recovery. But when early surgery is clearly indicated, it in no way jeopardizes outcome. In fact, it frequently wards off deformity and improves the ultimate result.

Through the program of the National Foundation for Infantile Paralysis, extension of aid to thousands of children and adults who have been stricken with poliomyelitis has been made possible. The policy of the foundation and its 2,800 or more chapters has been to spare no expense in seeking a preventive, and to provide care for victims of the disease. But now after the severe epidemics and drain on the resources of the foundation during the last few years, it may be well to consider whether or not certain economies may be practiced without detriment to any individual patient.

Little can be done to shorten the time of the acute febrile phase of the disease in the general hospital contagious ward, but great economy can be effected if patients can be released from isolation care, as is now generally felt to be safe, at the end of one week or when fever ceases. This would permit earlier discharge for outpatient follow-up of the almost 50% of patients who recover without significant weakness or paralysis and permit great reductions in expenditures for hospital care. Of course, early institution of good care during the isolation period will also do much to hasten recovery.

In the hospitals where treatment is given in the subacute, convalescent, and reconstructive stages, economy may be considered in three aspects: (1) financial; (2) time or manhours of work; (3) time saved for patient. For patients needing assistance, hospital costs have been borne wholly or in part by the local foundation chapter. The patient is treated in the inpatient department (weeks, months, and not infrequently for years) at an average daily cost of $13.00 to $20.00. He is then referred home and returns to the outpatient department for physical therapy and medical care, which, at an average cost of $3.00 a visit, extends for many weeks or months. Chapter treasurer's report for Dec. 31, 1948, showed $822,185 expended during the year for wheel chairs, crutches, transportation, braces, and similar items, or about 6.9% of the total spent. This does not cover epidemic nursing or the length of nursing service. Patients often are continued on physical therapy one to two years before surgical reconstruction is attempted or even recommended.

REEXAMINATION AND RECOMMENDATIONS

In my opinion, reexamination should be made of the usual method of giving physical therapy treatment for 12 to 16 months before surgical steps are taken. Instead a tentative plan of total care should be made for each patient. This should extend from the hot pack and passive motion stage through all aspects of therapeutic exercise, bracing, surgical reconstruction, and vocational training.

A thorough evaluation of performance, especially in relation to trunk muscle imbalances, should be made. Study of the muscle checks of 1,767 cases in the follow-up survey made by Dr. Robert Carroll of poliomyelitis patients from 1939-1942 and carried on under one of the earliest foundation grants shows that the recovery curve usually starts toward a plateau at the sixth month and flattens out about the eighth month. Occasionally, muscles show further improvement for six or eight more months. This report is in the files of the National Foundation for Infantile Paralysis and is outlined in a paper published in 1942.[1] As far as I know, it constitutes the largest study of its kind to date.

It is important to note whether the muscles showing improvement are those of the essential fixators which comprise the bases from which the intrinsic muscles of the legs and arms function. Essential for stabilization in the legs are the gluteals, quadriceps, and gastrocnemius, and in the trunk, the abdominal and lower spinal muscles. The abdominal musculature must be intact for stabilization of the pelvis in relation to the thorax and lower spine. The status may be determined by discovery of whether a positive Beevor's sign is present. If the umbilicus moves toward a viable segment of the abdominal musculature, positive fixation of the pelvis is lacking. If no action at all is present in the abdominal muscles, stabilization is also lacking. In the presence of either condition, it is impossible to estimate correctly the action of the leg muscles in relation to total performance. The use of physical therapy over a prolonged period (even though some individual leg muscles show improvement) will not lead to the desired stabilization. In fact, con-

[1] Carroll, R. L.: Rate and Amount of Improvement in Muscle Strength Following Infantile Paralysis, Phys. Therapy Rev. 22:243-257 (Sept.-Oct.) 1942.

tinued training of leg muscles in the presence of such abdominal weakness only tends to increase the gap in the kinetic chain and to provoke trunk deformity. Similarly proper fixation in the shoulder girdle must be provided to give good performance of the upper extremities. There the rhomboids, lower trapezius, serratus, and deltoids are most important. Continuance of intrinsic training of arm muscles in the presence of paralyzed fixators of shoulder girdle is a waste of time. Performance will remain limited unless repair is made.

Early surgical intervention directed toward attainment of the all-important trunk fixation will not only shorten treatment time by many months, but will also hasten the date of maximum performance. When the signs mentioned above are clear, repair at any time from the third to fourth month is none too early. Such intervention will save the time spent in hospital or convalescent home and the time of all persons involved in the care of the patient. Cost of hospitalization and physical therapy will be sharply reduced.

It should be stressed that many operations, especially those involving invasion of growing bone, are advisable only when a roentgenogram demonstrates the appropriate time. But certain tendon transplants, soft tissue surgery, such as that in the hand to improve opponens function of the thumb, can safely be done early. Early operation should also be resorted to if indications are clear that deformity is impending. In the presence of strong overactive or normal opponents to weak or inactive muscles, conservative physical therapy treatment should not be long continued. The discrepancy cannot be overcome by such means. Electromyographic studies show that muscles graded zero, trace, or poor do not recover, even with two years of treatment.

The record on the muscle chart does not necessarily give a complete picture, and the parents must be given to understand that it is only a guide to be used in execution of the plan previously explained.

An example is a girl, 6, with a dangle foot and no quadriceps function. The child wore a full length brace with locked knee joint to prevent a contracture deformity at the knee. For six months the monthly muscle chart showed overacting hamstrings and no quadriceps function. Since hip joint control was good, I did a biceps-to-patella transplant. This permitted cutting down the brace to a short below-knee size to control the foot and changed stiff-legged action to hip and knee action. Three months after operation the child could go up and down stairs normally. Of what use would it have been to have continued this child on exercises for 12 to 16 months? It was evident from the beginning that this operation finally would have to be done.

Another example is a boy, 9, whose bone structure of the foot showed good development. Muscle checks continuously showed strong gastrocnemius and peronei but wholly inadequate anterior and posterior tibialis. By the eighth month the surgeon saw that a subastragalar stabilization followed by transplant of one or both peronei would be necessary. These operations were successfully done and months of unnecessary physical therapy avoided.

If the parents have been made to realize that a careful plan of total care has been set up which will save time, work, and funds for all concerned, they will accept more willingly desirable changes from one modality of treatment to another and be ready to cooperate when the recommendation for surgery is made. If they understand that a return to reeducational exercise after each surgical procedure will be necessary, they will realize that prolonged exercise before operation is a duplication of effort. If they also understand that operations devised to correct imbalances of essential basic fixators are vital to performance, they will accept more readily necessary operations to foster speedier improvement of function.

Auxiliary workers, particularly physical therapists, sometimes encourage unwise continuance of physical therapy, and since practitioners who are not well versed in the care of poliomyelitis patients depend greatly on the therapist's view of the case, the physical therapy phase may be continued over a wholly unnecessary amount of time.

As another economy, effort should be made to train parents, public health personnel, and volunteer helpers to take over some home physical therapy treatment of poliomyelitis patients. If a weekly or biweekly treatment is given by the physical therapist at the clinic, mild paralytic, paretic, and nonparalytic patients usually do well under supervised home care. Muscle checks each fourth to eighth week will show whether or not progress is being made.

SUMMARY AND CONCLUSIONS

My recommendations are (1) an over-all plan for the patient through all stages of treatment with evaluation of the physical therapy aspects of care; (2) a thorough evaluation of performance, especially in relation to trunk muscle imbalance and potential deformity factors; (3) early surgical reconstruction when necessary and advisable; (4) an all-around increased effort to conserve patients' and workers' time and personal and institutional funds by increase in the tempo of care of poliomyelitis patients to the highest point commensurate with careful consideration of the needs of each patient.

Periarteritis Nodosa.—Perhaps the most serious allergic disorder, in that it accounts for most deaths, is periarteritis nodosa. This arterial necrosis occurs in a few cases of intractable bronchial asthma; it accounts for death from serum sickness and is caused frequently by drugs, particularly sulfonamides. Although in many instances no evidence of allergy is evident, its appearance both clinically and experimentally as an expression of hypersensitiveness identifies it as an important allergic disorder. Without doubt the disease is encountered far more frequently than heretofore. . . . Doubtless much of the increase in incidence of the disease is due to sulfonamide drugs and their indiscriminate use.—Harry L. Alexander, M.D., Allergy, in Medicine of the Year, Philadelphia, J. B. Lippincott Company, 1951, page 35.

TARSAL ANOMALIES AND PERONEAL SPASTIC FLATFOOT

Frederick S. Webster, M.D., Lincoln, Neb.
and
William M. Roberts, M.D., Gastonia, N. C.

Recent literature on the etiology of peroneal spastic flatfoot, especially by Harris and Beath,[1] has stressed the role of congenital abnormalities in this condition. Sloman[2] in 1921, and later Badgley,[3] observed the association of fusion of the anterior process of the calcaneus to the navicular bone with this condition, though anatomically the anomaly had been described earlier.[4] A second type of tarsal anomaly, namely, a union between the talus and the calcaneus in the region of the sustentaculum, has been held by Harris and Beath to be a commoner and heretofore unrecognized cause of rigid flatfoot. These authors reported a group of 17 cases of peroneal spastic flatfoot in which 88% were the result of tarsal anomalies. Twelve consisted of a talocalcaneal bridge in the region of the posterior end of the sustentaculum tali, and three were calcaneonavicular bars.

Since the above report was published, we have been taking special roentgenographic projections on all cases with peroneal spastic flatfoot. These consist of a posterior oblique view of the heel, with a downward and foreward projection angle amounting to 45 degrees for visualization of the sustentacular joint, and an oblique view of the midtarsal region to demonstrate the calcaneonavicular bar. These views are most important in addition to the routine X rays since the anomalies cannot generally be demonstrated without them. As a result we have found anomalies in 14 of the 21 cases of peroneal spastic flatfoot. Eight of these cases consisted of calcaneonavicular bars, four bilateral and four unilateral; four of a talocalcaneal bridge, three bilateral and one unilateral; and two of both of these anomalies, both of which were unilateral. Thus, tarsal deformity was the etiological factor in two-thirds of our cases. The frequency of these anomalies has been overlooked due to the requirement of special radiographic projections for their visualization.

The cause of most cases of spastic flatfoot has been explained on the basis of reflex peroneal muscle spasm secondary to some irritative focus of the tarsal joints.[5] Organic changes as a cause of spastic flatfoot in children generally have been considered uncommon. Certainly the association of bony abnormalities with spastic or rigid flatfoot has been completely ignored by the majority of authors, with only a few exceptions.[6] Rheumatoid arthritis with deformity and rigidity of the foot may early simulate spastic flatfoot, but it is a distinct entity. The common underlying cause of the usual spastic foot appears to be the presence of tarsal abnormalities and the fusion of the calcaneus to the scaphoid and to the talus. This is particularly true of resistant and recurrent cases, and careful examination of these feet reveals a limitation of mobility even after subsidence of the acute episode. It is true that because of the relative rigidity of the foot there is some adaptive shortening of the peronei, but definite evidence of peroneal spasm can usually be demonstrated in children when they have complaint. This is especially true in the type caused by the presence of a calcaneonavicular bar.

Many of these feet do not show depression of the longitudinal arch associated with valgus deformity, and in some even the valgus of the heel is absent, but the foot is relatively rigid and the forefoot everted. It has been a common previous observation that many of these so-called peroneal spastic flatfeet have not had a depression of the longitudinal arch and have frequently been unilateral. Most of such feet, we feel, would exhibit one or both of the tarsal anomalies here described if a thorough search were made for them.

THE CALCANEONAVICULAR BAR

This anomaly consists of a union between the anterior process of the calcaneus and the navicular. It may consist of a complete bone bridge (synostosis), a dense fibrous tissue bond (syndesmosis), or a cartilaginous bond (synchrondrosis). Pfitzner[4a] suggested that the anomaly resulted from fusion of a rare accessory tarsal bone, the calcaneus secondarius, to the calcaneus and the navicular. This anatomical study was published some 50 yr. ago.

Anomalies of this nature always exhibit restriction of lateral tarsal motion which may be proportional to the degree of osseous fusion. It is noteworthy, however, that the foot may not be flat in the sense that the longitudinal arch is flattened and the head of the astragalus depressed. The foot may be rigid though and held in valgus position due both to the anomaly and to the secondary peroneal spasm.

The onset of complaint is usually around the age of puberty or shortly before, during the active period of skeletal growth of the foot. As suggested by Badgley, the anomaly probably influences the functional structure of the tarsus most at that time. Generally these feet have manifested some degree of rigidity since early childhood. Minor trauma may initiate the symptoms of painful spasticity. Examination of these feet shows, in addition to the peroneal spasm and the limitation of inversion-eversion mobility of the forefoot, localized tenderness over the region of the calcaneonavicular bar. Rest will cause the

peroneal spasm to subside, after which the relative rigidity can be demonstrated. In younger children about the age of puberty the subastragalar motion may be only moderately limited. Abnormal stress on the midtarsal joint as a result of fixation of the bar brings about arthritic changes the most notable of which is an osteophytic lipping of the dorsolateral margin of the head of the astragalus. Harris and Beath state that this is invariably associated with these anomalies. While this is generally true, some of our younger cases did not show these changes while others not having congenital anomalies exhibited severe development of osteophytes. Likewise, older patients with these anomalies, but without symptoms, failed to show any evidence of tarsal arthritis. However, all the older symptomatic cases manifested this change on x-ray.

This anomaly may be unilateral or bilateral and may form a complete osseous bar uniting the calcaneus and navicular, or the bar may be incomplete with a connecting bond of fibrous tissue or cartilage (fig. 1).

CASE HISTORIES

Again, referring to Harris and Beath, these authors felt that, in contrast to the talocalcaneal bridge, the calcaneonavicular bar might be present without producing either deformity or disability. Probably the same holds true for both conditions since one of our cases of a talocalcaneal bridge had no symptoms, though in all cases there was limitation of mobility. The symptomatic types of calcaneonavicular anomaly have been grouped into syndromes. (1) Those with long-standing complaint originating in early childhood. The deformity need not necessarily be severe, but persistent pain and weakness characterize this type. The rigidity of the foot, especially forefoot, is unremitting. (2) Those without symptoms or deformity (other than some valgus position of the heel, perhaps, and some restriction of the inversion-eversion movements of the forefoot) until the patient suffers a wrenching injury to the foot. The peroneal spasm and rigidity may subside on conservative measures over a period of time, but the inversion-eversion movement of the tarsus is never of normal degree. These patients may become asymptomatic insofar as the pain and spasm are concerned but remain susceptible to exacerbation on future trauma. (3) Those in which there may be actual fracture of the bar. This is theoretically a possibility but has never been demonstrated. It might be better to classify as a third syndrome those patients who have had no known complaint in previous childhood, but who develop onset of symptoms shortly before puberty and in whom the disability persists. In general the majority of cases date onset around the age of 9 or 10 yr. Some of the syndromes and variations can best be illustrated by the following case histories.

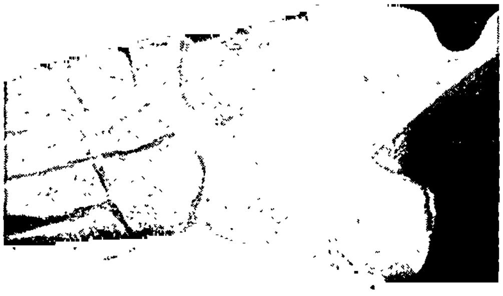

Fig. 2.—Lateral oblique view of the right foot (case 1) showing the calcaneonavicular synchondrosis. There was no arthritic change evident on lateral projection. This was an 11-yr.-old boy with similar anomalies in both feet.

Case 1.—*Bilateral Calcaneonavicular Synchondrosis.*—An 11-yr.-old white boy had foot complaints since the age of 7 yr. Because of continued stiffness and intermittent pain he was unable to run or play ball. Two weeks prior to his hospital admission he was unable to walk after a moderately long hike. Interestingly, this patient exhibited a definite varus tilt in the heels in weight-bearing, and he overran his shoes on their outer borders (fig. 3). Most of the varus tilt was on the right. Because of this he had been treated for some time with outside wedges to his shoes, but he never had complete relief from any type of support.

Physical examination revealed bilateral varus position of the heels with weight-bearing, especially on the right, and marked limitation of inversion-eversion motions of the forefoot. Repeated attempts passively to invert the foot resulted in peroneal spasm and rigidity of the foot. Passively, mobility of the os calcis was quite free bilaterally, though not of normal degree. Passive abduction of the forefoot caused pain in the region of the bar, and the patient was tender locally over that area. Roentgenograms showed a calcaneonavicular bar on the oblique view which was incomplete bilaterally (fig. 2). There was no evidence of osteoarthritic changes, and posterior oblique views revealed normal subastragalar joints.

Treatment consisted of excision of the bars. Under anesthesia relaxation of the peronei was obtained, and the feet could be inverted slightly beyond neutral position. There was, however, still marked limitation of motion. Upon direct visualization the bars were observed to possess a joint close to the base of the scaphoid. Each joint area was surrounded by a fibrous capsule, and minimal motion was noted on passive inversion-eversion movements of the feet. Midtarsal mobility was very limited. The bars differed somewhat in that the left one had a broader triangular base from the os calcis and projected anteromedially to a prominence of the lateral base of the scaphoid at an angle of about 55 degrees, while the bar on the right projected fingerlike at almost a right angle from the os calcis. Sections taken through the joint in the bar are shown in the photomicrograph (fig. 4).

Immediately after excision of the bars the feet could be passively carried through a normal range of inversion and eversion. The peroneal tendons did not cause any restriction, nor did they feel abnormally taut (fig. 3).

This case falls into the first syndrome. Resection of the bars was carried out because of the duration and severity of symptoms without evidence of arthritic changes or involvement of the subastragalar joints. In those cases with secondary osteoarthritic degeneration and restriction of subastragalar mobility a triple arthrodesis is preferable. In the five cases reported by Badgley resection of the bar was done in one and a subastragalar triple arthrodesis in another. Both operated cases had satisfactory results after a limited follow-up period. We feel that if arthritic changes are present or if there is an associated anomaly of the subastragalar joint, or both, then arthrodesis is the treatment of choice.

Case 2.—*Unilateral Calcaneonavicular Synchondrosis.*—A 14-yr.-old white boy turned his right ankle while running. Pain and stiffness of the foot persisted much longer than would be expected from a simple inversion sprain. He had had no previous complaints with his feet. Examination revealed moderate peroneal spasm with tenderness distal to the anterior talofibular ligament which corresponded to the site of the calcaneonavicular bar. There was marked limitation of lateral tarsal motion, and repetitive inversion movements of the foot threw the peronei into strong spasm so that subsequently no inversion could be performed passively. There was a good longitudinal arch to the foot, though the heel was slightly pronated. The Achilles tendon was not tight. The left foot was normal.

Conservative therapy was instituted which consisted of absolute rest from weight-bearing and whirlpool baths. The patient became asymptomatic after one month of treatment and has remained so to date, though lateral tarsal mobility of the right foot as compared with the left is limited. Roentgenograms revealed a calcaneonavicular bar on the right which was incompletely united (fig. 5). There were no other anomalies and no arthritic changes present.

This case illustrates the second syndrome which can be explained as caused by avulsion of the bar at the region of fibrous or cartilaginous union. A similar case was seen in which the patient had no complaints four years following the original acute episode. He had bilateral incomplete bars and was asymptomatic on recent examination, though his feet showed limitation of tarsal mobility. Also, there was no evidence of tarsal arthritis.

In general, feet possessing this anomaly show, with exception, some valgus position of the heel, though the longitudinal arch may or may not be depressed. There is limitation of the inversion-eversion movements of the foot. Subastragalar motion is not limited to the degree of midtarsal mobility unless there is secondary arthritic change or an additional talocalcaneal bridging. During acute episodes there is localized tenderness and pain over the region of the calcaneonavicular bar. Arthritic changes of the tarsal joints are frequently first manifested by osteoarthritic lipping of the dorsolateral margin of the head of the astragalus. This is proportionate in severity to the degree of valgus position and depression of the arch rather than to the completeness of osseous union of the bar.

THE TALOCALCANEAL BRIDGE

This tarsal anomaly consists of a bridge of bone spanning the subtalar joint and uniting the calcaneus with the talus immediately behind the sustentaculum. It may consist of a complete solid bony bridge (synostosis talocalcanea), or it may be incomplete with a fibrous bond (syndesmosis) or cartilaginous bond (synchondrosis) between the calcaneus and talus. An accessory joint may even exist. This has been attributed by Pfitzner and other anatomists to be the result of fusion of an accessory tarsal bone, the sustentaculum tali, to the astragalus and os calis. It occurs, when present, at the posterior end of the sustentaculum tali. The bridge may be united in part by cartilage and in part by bone.

In these cases there is fixation of the talus to the calcaneus, and the heel resists subastragalar motion. Osteoarthritic lipping usually is present on the dorsolateral margin of the head of the astragalus and is present more often in younger patients than in those with the calcaneonavicular bar. There is some valgus position of the heel, but the longitudinal arch may or may not be depressed. On careful clinical examination an abnormal fulness may be noted posterior and inferior to the medial malleolus at the site of this bony mass. Harris and Beath feel that this anomaly probably always causes deformity and disablement, but a patient in one of our cases had no complaints though the foot was in slight valgus position and moderately rigid. Again, complaints may arise about the age of puberty or in earlier childhood. Also, this anomaly has been found to occur in more than a single member of a family. Two cases of this anomaly studied in this series occurred in sisters, and they gave a history of an uncle who exhibited similar deformity, though he was not available for examination.[7]

CASE 3.—*Bilateral Talocalcaneal Synchondrosis.*—A 19-yr.-old white girl began to complain of her feet at about the age of 10 yr. The onset of her foot trouble accompanied minor trauma when she injured herself jumping from a height of several feet. Since then she has had increasing intermittent pain, swelling of the feet, and a tendency to "give way" in both ankles. At times the feet would become very rigid, and she could not invert them to any degree.

Physical examination revealed a good longitudinal arch bilaterally, though there was moderate pronation of the heels. Subastragalar motion was fixed, and the inversion-eversion movements of the foot were markedly limited. There was no peroneal spasm at the time of examination, though the patient stated that at times when she had pain in the feet they were held in valgus position and could not be inverted to the present degree. Most notable was a bony protuberance posterior and inferior to the medial malleolus which was due to the abnormal talocalcaneal union (fig. 6). This was not tender locally, but forceful passive joint motion caused pain in the region of the bridge.

Treatment in this case was subastragalar triple arthrodesis. The mass was excised from the medial aspect of the foot, and the synchondrosis is well demonstrated on microscopic section (fig. 8).

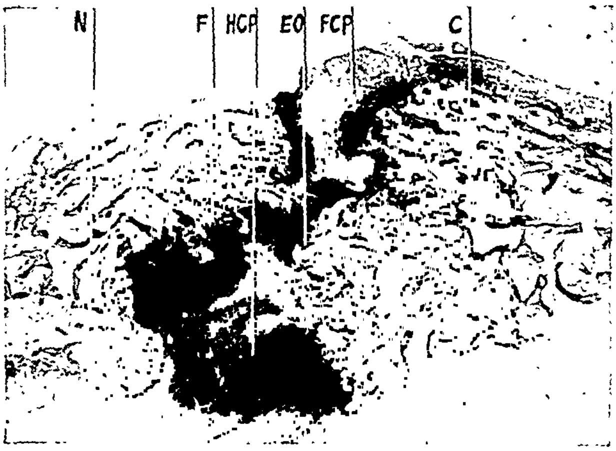

Fig. 4.—Low-power magnification of microscopic section taken through excised calcaneonavicular bar seen in roentgenogram of foot in figure 2. Two masses of essentially normal-appearing bony trabeculae; one from the anterior process of the calcaneus (*C*) and the other from the navicular (*N*) are separated by a plate of hyaline (*HCP*) and fibrocartilage (*FCP*). There is active endochondral ossification (*EO*) along the margins of the plate and areas adjacent to the cartilage in which the bone marrow is fibrotic (*F*). (Histological sections are from the Department of Pathology, Charlotte Memorial Hospital, Charlotte, N. C., by courtesy of Dr. Paul Kimmelstiel, pathologist).

In this case the anomaly could be identified on the lateral and anteroposterior roentgenograms, which ordinarily is not possible. It demonstrates very clearly the position of the talocalcaneal bar posterior to the sustentaculum tali (fig. 7). The anomaly in this case exhibited a familial tendency. The 26-yr.-old sister of this patient had an identical condition without any complaint except for an occasional "aching" in the calves (fig. 9).

With this anomaly complaint is usually of early onset, or the foot may remain entirely asymptomatic. The asymptomatic foot does not seem to possess the susceptibility to trauma that occurs in some cases of calcaneonavicular bar, and the symptomatic foot does not respond to conservative therapy as do, in certain instances, cases of other foot anomalies. Neither anomaly is peculiar to race.

---

[7] These were patients of Dr. Julian Jacobs of the Miller Clinic, Charlotte, N. C. and were studied and presented with his permission.

ROENTGENOGRAPHIC FEATURES

The position of the talocalcaneal bridge posterior to the sustentaculum tali as described anatomically is well illustrated by figure 7. Sometimes the synchondrosis can be distinguished as a thin serrated line of decreased density between the bone masses. This serrated margin has also been described anatomically and may be apparent on lateral films of the foot (fig. 10). On the posterior oblique view the bone mass and line of synchondrosis are visualized inferior to the level of the normal sustentacular ledge and joint line as they lie posterior. The abnormal bone mass is of greater magnitude than the normal sustentacular process, and at times the line of synchondrosis is directed inferiorly and medially (fig. 11). There may also be a varying degree of osseous union.

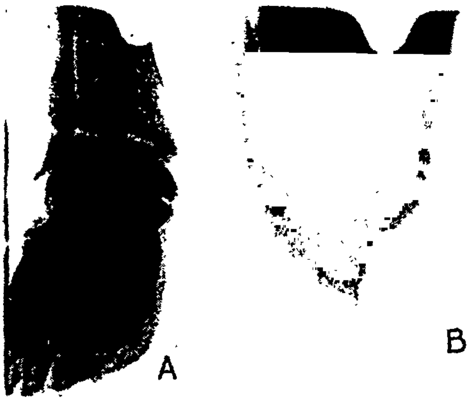

Fig. 6.—Talocalcaneal bridge of the left foot (case 3) showing the anomaly inferior to the medial malleolus on a routine anteroposterior view of the ankle (*A*). This film is reversed for better comparison with the posterior oblique view (*B*) of the same anomaly.

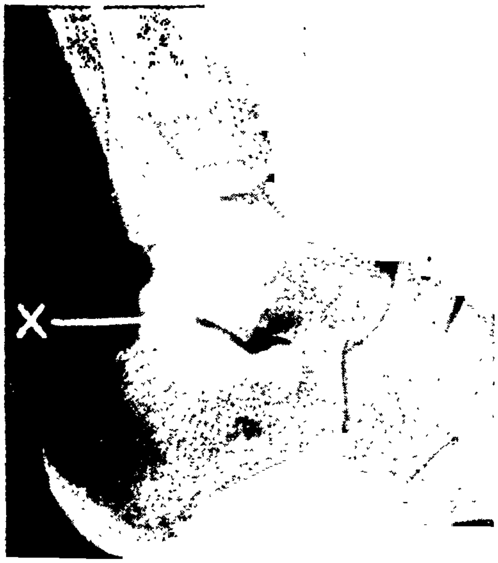

Fig. 7.—Lateral view of the foot shown in figure 6. The talocalcaneal synchondrosis can be identified as a narrow serrated line posterior to the sustentaculum tali. The anomaly cannot usually be demonstrated on a routine lateral film.

The lipping of the dorsolateral margin of the head of the talus may or may not be evident early, but it is more frequently observed in cases of talocalcaneal bridge than in cases of calcaneonavicular bar. Arthritic lipping is especially significant of tarsal anomaly when it is in combination with a good longitudinal arch and a young foot (*fig. 11*). Similar changes may occur in severe flatfeet without anomalies. In unilateral cases of these anomalies a severe flatfoot on the opposite extremity may show a greater degree of arthritic change and deformity of the arch than the side with the congenital abnormality. The symptoms are greater, however, on the side with the anomaly. The relative rigidity of the foot probably accounts for the lesser degree of tarsal arthritis in such cases. The symptoms are not proportionate to the extent of the osseous union of the anomaly. Also, tarsal arthritis in feet possessing these anomalies is not a prerequisite for complaint, yet no asymptomatic foot in our series revealed evidence of degenerative arthritis.

MICROSCOPIC FEATURES

The majority of these anomalies possess an area of synchondrosis. Microscopic studies reveal cartilaginous plate consisting of both fibrous and hyaline cartilage between the anomalous bone masses which are composed of normal trabeculated bone. The plate is of varying width and usually shows evidence of active transformation into osteoid and bony material along the margins where it is in direct continuity with the adjacent bone (fig. 4 and 8). Thus, with increased ossification with age one might expect complete obliteration of the plate of cartilage through ossification. In the series of cases presented here all those under the age of 14 exhibited a synchondrosis. The width of the plate generally was indirectly proportional to the age. This is illustrated in two of the older patients with calcaneonavicular bars. The one, 22 yr. of age, had an incompletely ossified bar (fig. 12). The other, 24 yr. of age, had a completely ossified bar (fig. 1).

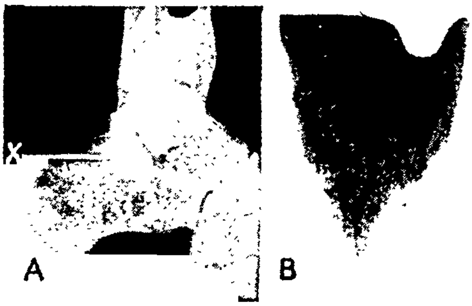

Fig. 9.—Lateral (*A*) and posterior oblique (*B*) roentgenograms of a foot of the sister of a patient in case 3 (fig. 6 and 7). This was a 26-yr.-old woman with bilateral talocalcaneal anomalies who had never had complaint with her feet, though they were relatively rigid. There is no evidence of tarsal arthritis, and, generally, the feet are almost identical to those in case 3, though there is a greater degree of osseous union of the talocalcaneal bridge.

Trauma with callus formation is a second process ossifying the plate. Injury to the plate can explain the localized complaint common with these anomalies and is, in addition to the arthritic degenerative changes, a cause of symptoms. In the cartilaginous plate areas may be found which show necrosis of cartilage and the formation of clefts (fig. 14). These degenerative changes are interpreted as the result of trauma. In young patients with a talocalcaneal bridge a mixture of chondrous and osseous union is frequently observed. This probably is due largely to callus formation (fig. 13). Such an interpretation can explain the clinical observation that this anomaly, once it has become symptomatic, does not respond to conservative therapy. The role of trauma is more prominent due to the subastragalar position of the talocalcaneal bridge.

There was no evidence of an accessory bone in any of these cases. The presence of separate bone masses is much uncommoner than these anomalies.[8] We have seen one case in addition to this group of calcaneonavicular and talocalcaneal anomalies with a separate area of ossification. This was a case in which the sustentaculum tali was partly adherent to the talus and did not restrict tarsal mobility or cause symptoms (fig. 15). Thus, the os secondarius and sustentaculum tali are probably a part of the same abnormal process since studies on the fate of other accessory tarsal bones, such as the accessory scaphoid, have shown that fusion occurs between that bone and the scaphoid in a large proportion of such cases in which a separate accessory bone was roentgenographically demonstrated.[9]

Another occasional tarsal bone, the talus accessorius, may also contribute to the formation of the talocalcaneal union. This is suggested by the position and magnitude of the anomaly as frequently encountered. In addition, the frequent occurrence of the area of synchondrosis in the inferior portion of the abnormal bone mass suggests primary osseous union with the talus.

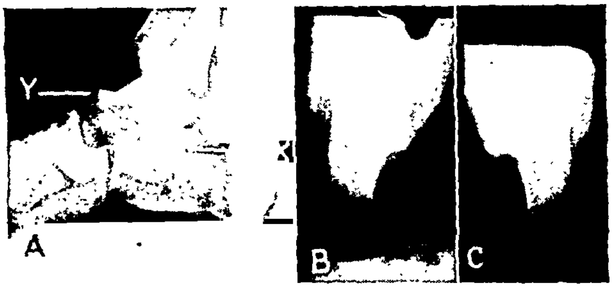

Fig. 11.—Osteoarthritic lipping of the head of the talus in the presence of a high longitudinal arch in the foot of a 13-yr.-old girl with a talocalcaneal synchrondrosis. The anomaly is not well visualized on the lateral film (*A*), though the narrow space marked by *X* between the posterior margin of the sustentaculum and the talus is suggestive. A normal talo-sustentacular joint is shown (*B*) in contrast with the anomaly as visualized from a posterior oblique view (*C*).

TREATMENT

In the treatment of spastic flatfoot the early recognition of tarsal anomaly as the etiological factor in its production is important. The plan of therapy varies somewhat depending upon the anomaly, the type of syndrome, the age of the patient, and the degree of secondary arthritic involvement.

Conservative Measures.—These are primarily reserved for cases which have only an occasional complaint following trauma and for cases of symptomatic talocalcaneal anomalies in children too young for arthrodesis of the foot. The former cases consist of those with a calcaneonavicular bar exhibiting the second type of syndrome. In these absolute rest of the foot, aided perhaps by whirlpool baths, will cause the acute symptoms of spasm and fixation to subside, but treatment is required over a moderately long period of time and normal flexibility of the foot is never obtained. Consistent support is maintained through the use of firm rubber arch pads. Plaster immobilization under anesthesia is of value since it allows maximal relaxation of the peronei and maintains support of the foot, though usually the same result may be accomplished through rest and whirlpool baths. Manipulation in itself is of no value and actually may be harmful. The rigidity resulting from the anomalies themselves after release of the peroneal spasm does not further improve under anesthesia, and forcing correction is either futile or causes additional injury to the region of congenital abnormality which was the exciting factor originally.

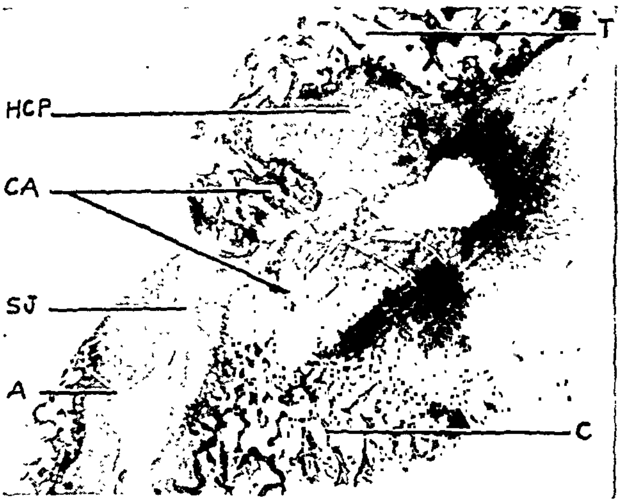

Fig. 13.—Low-power magnification of microscopic section taken through the excised talocalcaneal anomaly of the foot whose roentgenograms are reproduced in figure 10. A hyaline cartilage plate (*HCP*) separates the bone mass of the talus (*T*) from that of the calcaneus (*C*). There is an area of callus (*CA*) in which there is formation of osteoid and bony material extending across the cartilaginous plate at its medial border. This lies between the remaining lateral portion of the cartilage of the synchondrosis and the sustentacular joint (*SJ*). The defect in the articular cartilage (*A*) of the joint is the site of degenerative arthritis.

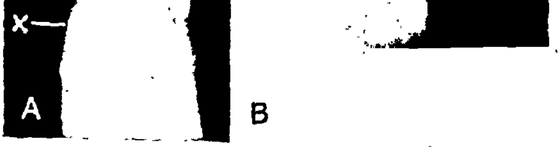

Fig. 15.—Sustentaculum tali (*A*) present in an asymptomatic foot. This was a 20-yr.-old athlete who exhibited only slight valgus position of the involved foot without any restriction of subtalar motion, arthritic changes, or previous complaint.

Surgical Measures.—(1) Calcaneonavicular bars: In young children and feet without arthritic changes the bar

should be resected as early as it is recognized (fig. 16). These feet may be subject to recurrence of painful spasticity if unrecognized subastragalar changes are present, however, and a triple arthrodesis will then be required. In older cases with arthritic degeneration and rigid, deformed flatfoot, arthrodesis is the procedure of choice. (2) Talocalcaneal bridge: Arthrodesis is the treatment if symptoms warrant it and should be done as soon as osseous development of the foot permits it.

SUMMARY

The commonest cause of peroneal spastic flatfoot is tarsal anomaly consisting of a calcaneonavicular bar or a talocalcaneal bridge. Either or both anomalies may be present. Such feet exhibit some degree of rigidity even when without symptoms. However, in children during acute episodes peroneal spasm in addition is present which holds the foot in rigid fixation. Most of these feet show some degree of valgus position, though in many there may be no depression of the longitudinal arch. In the latter type foot tarsal arthritis with lipping of the dorsolateral margin of the head of the talus is significant of congenital anomaly. The presence of these abnormalities has been overlooked because of the difficulty of visualization on routine roentgenography. These anomalies usually possess an area of synchondrosis, the cartilage of which is progressively transformed into bone to varying degrees. Formation of bone through callus probably accounts for the early osseous fusion frequently found with the talocalcaneal bridge. Treatment is dependent upon the anomaly, the type of syndrome, the age of the patient, and the degree of secondary arthritic change. Early recognition of the etiology of the peroneal spastic flatfoot influences the treatment and prognosis.

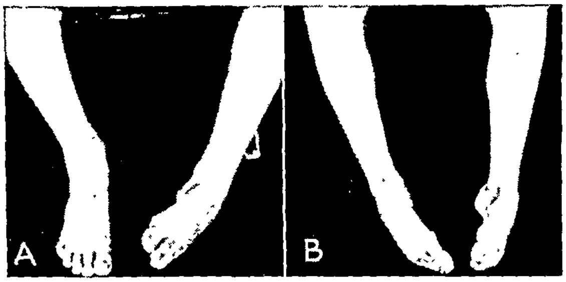

Fig. 16.—Eleven-year-old boy with a calcaneonavicular bar in the right foot who illustrates the third type of syndrome. Rigid valgus position of the right foot is shown in (*A*) before surgery. The release of tarsal rigidity is brought out by the postoperative photograph (*B*).

1108 Sharp Building (Dr. Webster).

ABSTRACT OF DISCUSSION

Dr. Earl D. McBride, Oklahoma City: Dr. Webster and Dr. Roberts have added further convincing evidence that the congenital anomalies between the calcaneus and astragalus, or calcaneus and scaphoid, may be specifically responsible for the clinical phenomenon known as spastic flatfoot. They have mentioned that these deformities have been overlooked frequently, but I would say they simply have not been looked for. Constant stressing of the necessity for oblique roentgenographic views of children's feet may eventually improve the statistics. The feet of small children seldom present symptoms of pain, no matter how pronated or flattened the arches may appear. When the child does complain of his feet or legs, and when rigidity of the tarsal joints is at all present, some of these anomalies may be responsible. Such a foot should be followed into maturity with periodic roentgenograms. Spastic flatfoot is comparatively rare. It still is not known what percentage of feet with these intertarsal anomalies do or do not develop into peroneal spastic flatfoot. So far as I can recall over a period of 30 yr. good results have been obtained from closed, forcible manipulation of the peroneal spastic flatfoot, followed by six or seven weeks of immobilization in overcorrecting weight-bearing casts. Of course, the contour of the arches, in such cases, usually remains flattened, but the ultimate result is satisfactory when adequate support and exercises are applied. Dr. Webster did not say much about treatment; however, in his paper he does recommend surgery in many of these cases and removal of the anomaly. Too much enthusiasm for surgical removal of these anomalies, based on roentgenographic discovery, might lead to inadvisable and mutilating surgery. When removal of the anomaly is necessary, as in the presence of spastic flatfoot, it would seem advisable to proceed with fusion of a type which will correct the flatfoot. I would strongly stress against surgical meddling with a child's foot through enthusiastic curiosity. I feel that we should not become too enthusiastic about surgical treatment in these cases. I do think we should become more enthusiastic about x-raying of children's feet from the standpoint of these anomalies.

Dr. Charles Young, Los Angeles: I wish to bring out some of the background of tarsal anomalies and spastic flatfoot. Previous to 1900 all cases of flatfoot were put in the broad classification of flaccid or rigid. In 1905 Sir Robert Jones described an entity which he called peroneal spasm in flatfoot. As treatment he tenotomized the peroneal tendons and manipulated the foot with a Thomas wrench until it was flexible. Plaster was applied to maintain a position of inversion and adduction. There must have been relapses because, later, he recommended the excision of a ¾ in. section from the peroneal tendons to prevent them from reuniting. We know now that muscle spasm, and not adaptive shortening, is caused by arthritic changes in the foot. A decade later Jones described another entity which he called osseous flatfoot, the foot being in a rigid deformed position but without spasm of the peroneal muscles. He was misled by the presence of osteophytes on the superior margin of the talonavicular joint. These are the result of rigidity caused by tarsal anomalies, not by true osteoarthritis. Jones did not know the etiology of this osseous flatfoot, as we have heard it described today. I am in agreement with the treatment described by the essayists. Adults with calcaneonavicular bars which are painless require no treatment. Conservative treatment can be used in painful cases, unless the pain is persistent; then surgical intervention is necessary. Patients with talocalcanean bridges have more pain, do not respond well to conservative treatment, and usually require operations. When an arthrodesis is performed on the subtalo and calcaneonavicular joints, in severe cases, it should include the calcaneocuboid joint; otherwise, correction of the deformity is difficult after division of restraining soft structures, and a good result is not so sure. When these anomalies are discovered in childhood and conservative treatment fails, operations should be postponed until the teen-ages when, as determined by roentgenograms, the tarsal bones have almost completely ossified.

Swimmer's Itch.—Swimmer's itch, or schistosome dermatitis, is a water rash found in . . . the region of the Great Lakes. It is caused by penetration into the skin of flukes known as cercariae. It does not result in disease to humans but is objectionable because of the extreme discomfort it causes. . . . The causative organisms are found living in the tissues of common snails, from which they emerge daily during warm summer weather. Bathers are infected by accidentally capturing the organisms in drops of water on the skin and allowing them to penetrate. Once inside the skin, the defensive mechanism of the body destroys them, resulting in local irritation around each point of entrance. A severe itching or burning sensation is the result. Bathers may prevent penetration of the skin by these organisms by drying the body completely and briskly with a towel immediately on leaving the water, or by taking a shower in cercaria-free water before the beach water dries on the skin.—Theodore F. Wisniewski, Aquatic Nuisance Control, *Wisconsin Medical Journal,* June, 1951.

CRYPTOCOCCUS (TORULA) MENINGITIS

REPORT OF TWO CASES

Albert W. Cook, M.D., Brooklyn

Human cryptococcosis (torulosis) was first recognized as a clinical entity in 1914 by Versé.[1] Previous reports by Busse and Buschke,[2] Gilchrist,[3] and Curtis [4] at the end of the 19th century, however, indicate that they had actually described Cryptococcus infections in man but had not classified the yeast as Cryptococcus hominis (Torula histolytica). Since that time three monographs [5] and innumerable articles have appeared in the world literature describing the characteristics of human infestations with this organism, and to date approximately 200 cases have been reported.

Although acute forms of the disease have been known, typically human Cryptococcus infections are of a chronic nature and most commonly implicate the central nervous system and lungs. Isolated instances of recovery have been cited,[6] but death is the expected termination of the disease. No specific mode of therapy is known.

In spite of an increasing number of reports of this malady, few diagnoses have been made before death and, in fact, it is still considered a rare clinical entity unfamiliar to many physicians.

The purposes of this report are several: to record two additional cases, one being recognized before death, encountered in the wards of two general hospitals in 15 months; to call attention to the various manifestations of infection in the nervous system with the Cryptococcus organism, with its problem of diagnosis; to express the view that human torulosis may not be as rare a clinical problem as has been heretofore believed; and finally, to indicate various syndromes in which Cryptococcus infections should be considered instead of assuming the existence of some other process without positive substantiation.

CASE REPORTS

CASE 1.—J. W., a woman aged 58 years, was admitted to the Brooklyn Hospital under the care of Dr. Warren Huber, with the complaint of severe headaches for the previous 39 days. These headaches had appeared three days after a smallpox vaccination and were located at the vertex of the skull. Large doses of acetylsalicylic acid afforded no relief. Three weeks prior to admission she had noted that her speech was indistinct and that she had trouble forming words. Diplopia appeared shortly thereafter, and her vision had progressively failed up to the time of admission. Members of the family had also observed that she was increasingly more somnolent and that her vision seemed to be impaired when viewing objects on the left side. Gold circles had been seen in both the right and the left visual fields.

Examination.—The blood pressure, pulse, respiration, and rectal temperature were all normal. Neurologic examination revealed the following abnormalities: (1) enlarged left pupil which reacted promptly to light directly and consensually; (2) internuclear ophthalmoplegia; (3) nuchal rigidity and bilateral Kernig's signs; (4) a left homonymous visual field defect (confrontation); (5) bilateral papilledema; (6) marked error of projection in the performance of the finger to nose test bilaterally and to a less extent in the heel to knee test; (7) absent superficial abominal reflexes, and (8) bilateral signs of Babinski. There were no changes in sensation, muscle reflexes or in the function of any of the other cranial nerves. Her speech difficulty was primarily that of an inability to form words and enunciate correctly. She was able to obey visual and auditory commands promptly and accurately and all objects and their uses were appreciated correctly.

During the course of the examination her position was changed from a supine to a sitting attitude. Upon return to the former her condition changed suddenly. Her head turned from side to side, and vertical nystagmus was detectable. The left upper extremity was thrown over her head and when she was asked to touch her nose, her hand traveled in all directions, finally landing on her face with a thump. She said "I'm so sleepy, so sleepy all the time." In several minutes these signs disappeared and she became more lucid.

No abnormalities were found after a general physical examination except a fading maculopapular rash over her neck and shoulders. There was no local reaction at the site of vaccination. Roentgenographic examinations of the skull and chest were considered negative.

In view of the history of vaccination, a diagnosis of postvaccinal meningoencephalitis was entertained although the possibility of a chronic meningitis due to an organism such as the tubercle bacillus or C. hominis was considered by her physician.

On the day following admission, paresis of the right lower face and upper extremity appeared and a lumbar puncture showed clear and colorless cerebrospinal fluid under normal pressure. In order to exclude the slight possibility of a subdural hematoma, bilateral burr holes were appropriately placed. Since there was no evidence of recent or old subdural bleeding, air was introduced into the ventricular system and subsequent ventriculograms revealed no change in the size, shape, or position of the ventricles. The only significant finding was that of a large accumulation of cerebrospinal fluid within the subarachnoid space overlying the right cerebral convexity. On subsequent lumbar punctures the spinal fluid was yellow and contained from 200 to 350 cells, the greater proportion of which were mononuclear in type. The unusual large size of these cells prompted the laboratory technician to consult the clinical pathologist, who immediately appreciated their importance and after staining demonstrated numerous yeastlike bodies with gram-positive granules of varying size. The total protein and sugar contents of the spinal fluid were estimated on various occasions at 70 to 80 and 10 to 18 mg. per 100 cc., respectively. The colloidal gold curve was normal and the cerebrospinal fluid contained 763 mg. of chlorides per 100 cc. on one occasion. Culture of this fluid yielded a luxurious growth of C. hominis. The organism was then cultured on glycerin veal and Sabouraud's medium (incubated at room temperature for 18 hours) and found to be resistant to 100 Oxford units of penicillin and 1,000 units of streptomycin.

In spite of treatment with chemotherapeutic and antibiotic agents available at that time (before aureomycin, chloramphenicol and others), little improvement was noted in the patient's clinical course. Repeated spinal punctures continued to yield a

yellow fluid with an elevated total protein, a low sugar, and pleocytosis. She gradually lapsed into coma and died 21 days after admission to the hospital. Permission for an autopsy was not granted.

CASE 2.—E. A., a 19-year-old Negro youth, was first admitted to the hospital in June 1948, with the chief complaints of frontal headache and vomiting for the previous month. The headaches remained for a few hours and disappeared abruptly. At first there were no concomitant symptoms, but later nausea and vomiting and bilateral shoulder pain accompanied the attacks of headache. At one time numbness and tingling of the entire right upper extremity appeared but apparently remained for only a short time. Prior to the onset of these disturbances the only relevant symptom was that of staggering to both sides six months before entry into the hospital.

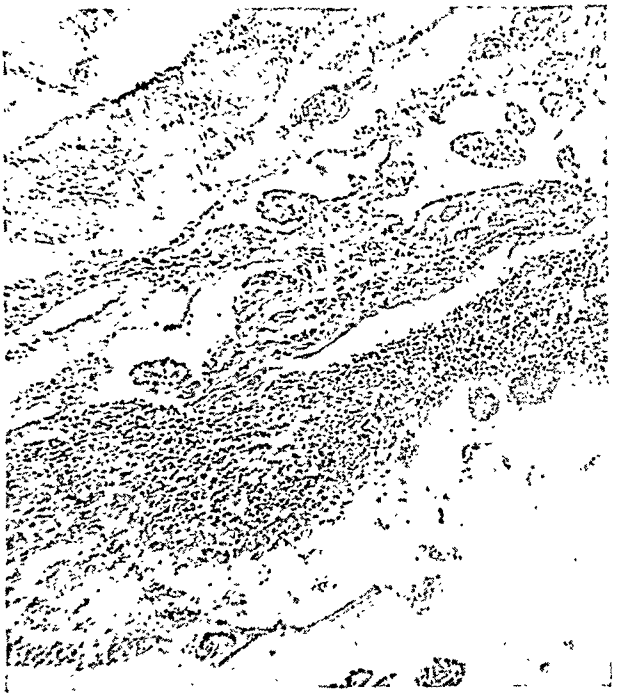

Fig. 1.—Granulomatous lesion and Cryptococcus organisms in the meninges. Hematoxylin and eosin; ×60.

Examination.—The blood pressure, pulse, respirations, and rectal temperature were all normal. The patient was poorly developed, lethargic, and despondent. The only abnormal neurologic findings were a tendency to stagger to the right when he walked with his eyes closed and bilateral papilledema of 3 to 4 D. His neck was not stiff, and hyperextension of the head on the neck did not produce additional symptoms. There was no impairment of the function of structures innervated by any of the cranial nerves other than the changes noted in the optic nerves. Visual acuity was normal on both sides, but perimetric examination of the visual fields disclosed bilateral enlargement of the blind spots and a concentric contraction of both fields. There was a female distribution of pubic hair, no axillary hair, no chest hair, and no facial hair. An electroencephalogram was interpreted as being normal.

Because of the patient's age and the symptoms and signs of increased intracranial pressure, a posterior fossa neoplasm was suspected but a subdural hematoma was also considered. Trephination of both the temporal and the occipital areas bilaterally revealed only a brain under considerable tension, without evidence of subdural hemorrhage (Dr. William Druckemiller). The posterior fossa was then explored. Here a very thick opaque arachnoid was seen over an enlarged cisterna magna. This was incised and found to be adherent to the underlying cerebellar cortex and overlying dura. The cerebellar tonsils had not herniated through the foramen magnum, and after thorough exploration nothing suggestive of a neoplastic lesion was found.

On the first postoperative day the rectal temperature was 101 F., but it returned to normal in 24 hours. The patient vomited frequently and complained of pain over the right eye. Sensation, reflexes, and motor power in all extremities remained unaltered. Lethargy persisted. On the fourth postoperative day a lumbar puncture was done and the cerebrospinal fluid was found to be grossly bloody under a pressure of 288 mm. No organisms were found in the fluid. The headache, vomiting, and lethargy continued for the next two days; then the blood pressure and pulse began to fluctuate. His respirations were interrupted by periods of apnea. Subsequent lumbar punctures alleviated these symptoms temporarily but with each succeeding day he became less responsive. On the 21st postoperative day the rectal temperature was subnormal and he was incontinent of urine and feces. From this time to his demise he was unresponsive and moist rales were heard at both lung bases on the 29th postoperative day. The latter increased markedly in the next ten days until he died, on the 39th postoperative day. The final clinical diagnosis was adhesive arachnoiditis of the posterior fossa due to an unknown cause.

Autopsy Findings.—In addition to passive congestion of the viscera the pertinent findings were confined to the brain and lungs.

Lungs: The lungs weighed 600 Gm. together. The right lower lobe was firm and nodular and the pleural surfaces were covered with a fibrinous exudate. The cut surface was marked by irregular, elevated, granular areas from which purulent material could be expressed. Microscopic examination of this tissue revealed two circumscribed areas of caseous necrosis, one with a suppurative center and surrounded by epithelioid cells and fibrous connective tissue. A few oval, semitranslucent bodies with refractile capsules suggestive of cryptococcus organisms were noted. There was a severe purulent bronchopneumonia, and acid-fast stains did not reveal any organisms suggestive of the tubercle bacillus.

Brain: The cerebral convolutions were approximately equal in size, but all the gyri were tremendously flattened, with obliteration of the sulci. The pia-arachnoid over the convex surfaces of the brain was thick and milky in appearance. There were dense adhesions between the cerebellum and the medulla, obliterating the foramens of Luschka and Magendie. Dense adhesions were found in the dura over the posterior surfaces of both lateral cerebellar lobes. On frontal section, the anterior horns of both lateral ventricles were greatly dilated, and the third ventricle moderately so. There were enormous dilatations of the posterior horns of both lateral ventricles and the aqueduct was moderately dilated. As one looked through the dilated fourth ventricle from

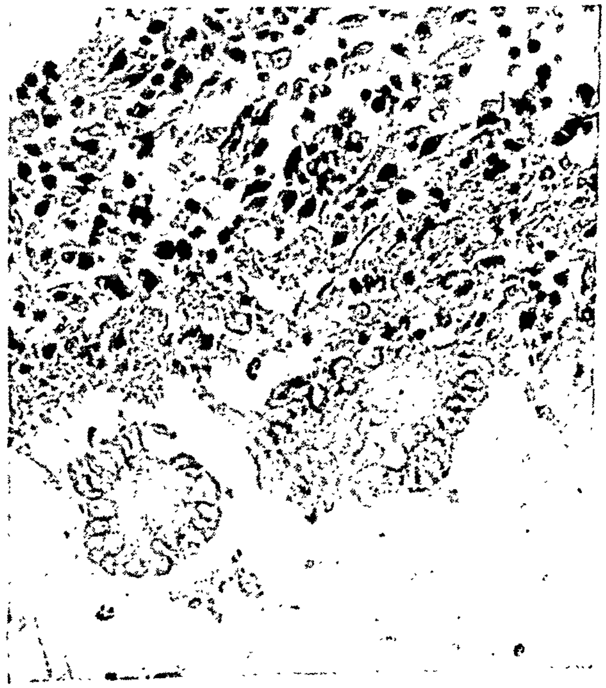

Fig. 2.—Granulomatous lesion and Cryptococcus organisms in the meninges. Hematoxylin and eosin; ×440.

anterior to posterior, the ependyma appeared granular and the foramina of Luschka were represented only by small depressions. There was no trace of the foramen of Magendie, and no communication could be found into the cisterna magnum. Microscopic examination of sections from the cerebellum and brain stem revealed an extensive and severe chronic granulomatous inflammation of the leptomeninges. The superficial layers of the brain were also involved in this process with several discrete lesions being placed at a much deeper level. The ependyma was similarly involved. The inflammatory process consisted of a poorly organized mixture of epithelioid cells, a few giant cells, plasma cells, lymphocytes, and an occasional polymorphonuclear leukocyte. Refractile spherical bodies with gelatinous capsules were found both within the giant cells and lying free in the exudate. Occasional small buds were noted on these organisms, which were very suggestive of C. hominis (figs. 1 and 2).

COMMENT

The sequence of events leading to the diagnosis of C. hominis infections in the central nervous system in these two cases is fairly representative of the experience of other authors. The clinical picture is, at first, confused with either meningoencephalitis from other causes, or subsequently, subdural hematoma and brain tumor are sought by trephination, ventriculography, and finally exploration. When, even after these procedures, the etiologic diagnosis is still not apparent, one must await the result of necropsy studies. Here, the great majority of diagnoses are made.

The crucial point in the antemortem diagnosis is, of course, the examination of the spinal fluid, and more particularly the isolation of the organism from this fluid. However, here there are many pitfalls. At times, as in the case of the first patient, the fluid may be clear and colorless when it is first examined, but most often it is yellow and has an elevated protein content. The organism, if thought of, may be easily visible and recoverable by culture,[7] yet even when visible it may be incorrectly reported as lymphocytes or red blood cells. In case 1 it was only because of the alertness of the laboratory technician in realizing that the cells he saw were unusually large that recognition by the clinical pathologist was possible. It can be readily appreciated how fortuitous this finding was, especially since an autopsy was not performed and undoubtedly the true diagnosis would never have been evident. When such cases appear in the younger age groups the common diagnosis is usually tuberculous meningitis even though an organism is never isolated. Similarly, in other cases of so-called chronic arachnoiditis, chronic serous meningitis and other vague forms of chronic meningitides, Cryptococcus infections should, at least, be considered. It is indeed significant that in the second patient the diagnosis was not evident until microscopic examination of the brain. In the past it was merely of academic interest to make such a differentiation, but with the ever-increasing availability of newer chemotherapeutic and antibiotic agents, it is incumbent upon the physician to attempt to substantiate his diagnoses in these cases from an etiologic standpoint so that a true evaluation of these new drugs can be made in diseases which are otherwise almost universally fatal.

SUMMARY

Two cases of Cryptococcus (Torula) meningitis are reported, one being recognized antemortem. The various manifestations and problems of diagnosis are mentioned and illustrated by the case reports. The view is expressed that human Cryptococcus infection of the central nervous system may not be as rare as is believed. Only future investigators will establish the value of searching for this organism in otherwise vague unsubstantiated chronic meningitides when the ever-increasing number of chemotherapeutic and antibiotic agents are used to combat it.

TREATMENT OF ACNE VULGARIS

George C. Andrews, M.D., Anthony N. Domonkos, M.D.
and
Charles F. Post, M.D., New York

Stuart Way and one of us (G. C. A.) recently reviewed the literature of acne vulgaris with especial reference to hormone imbalance.[1] The present paper simply describes an experiment. Two years ago we decided to try to use for a year only antibiotics and estrogenic substances in treatment of acne vulgaris and not to employ X-ray irradiation.

We had up to that time achieved some good results with antibiotics, estrogenic substances, and other modern medicines. This small success made us wonder whether modern medical progress had reached a point where acne could be cured by these remedies. Our success during this first year of the experiment was so satisfactory to all that we have continued the experiment through the second year without any misgivings as to its superiority over the older methods of treatment in vogue five or 10 yr. ago.

Whereas prior to the beginning of this experiment X-ray treatment was routinely used in practically all cases of acne and was considered essential, it was suddenly discovered that without X-ray treatment just as good, if not better, results were achieved. Indeed our most interesting cases were those in which the patients had received long series of X-ray treatments before coming into our hands. It was in those cases of the nodular and cystic type that had not responded to X-ray treatment that our most gratifying results were achieved.

From the Department of Dermatology, Presbyterian Hospital, College of Physicians and Surgeons, Columbia University.

This paper is the first in a "Symposium on Therapy," read before the Section on Dermatology and Syphilology at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 30, 1950.

[1] Way, S. C., and Andrews, G. C.: Hormones and Acne: Clinical Evaluation of Hormonal Therapy in Adolescent Girls with Acne, Arch. Dermat. & Syph. 61:575-588 (April) 1950.

The experiment was based upon certain concepts of fundamental importance. These concepts may differ from those generally held; they would not be worth reporting unless they did. We have, however, come to rely upon them as a result of our studies and experiences.

1. We assume that simple cases of oily seborrhea, comedones and papular acne (acne simplex) can be cured by a low-fat diet, the administration of vitamin A and diethylstilbestrol, the expression of comedones, and the use of orthodox local remedies such as lotio alba, sulfurated lime (Vleminckx's) solution, and remedies for the scalp.

2. Another assumption is that in pustular, nodular, and cystic cases the patients usually are sensitized to the Staphylococcus. They often harbor foci of infection which contribute to the pustulation and make it worse, if not being the sole cause. This view was expressed 20 yr. ago by one of us (G. C. A.) in the first edition of his textbook, and he was then reprimanded about this statement in the review of the book in the *Archives of Dermatology*. However, time has passed, and over and over again in these 20 yr. this concept has been borne out in practice. For example, one girl with pustular acne had pyelonephritis, and whenever the acne was bad the urine contained pus: As soon as urinary antiseptics cleared the urinary tract of infection, the acne disappeared. In another girl the acne was associated with chronic sinusitis, and the use of sulfathiazole nose drops and irrigation of the sinuses promptly cleared the acne. Several cases were promptly and spectacularly cured on the removal of impacted and infected wisdom teeth or badly infected tonsils, or after appendectomy. Sometimes we have failed to find foci of infection in pustular cases of acne, but often foci are present.

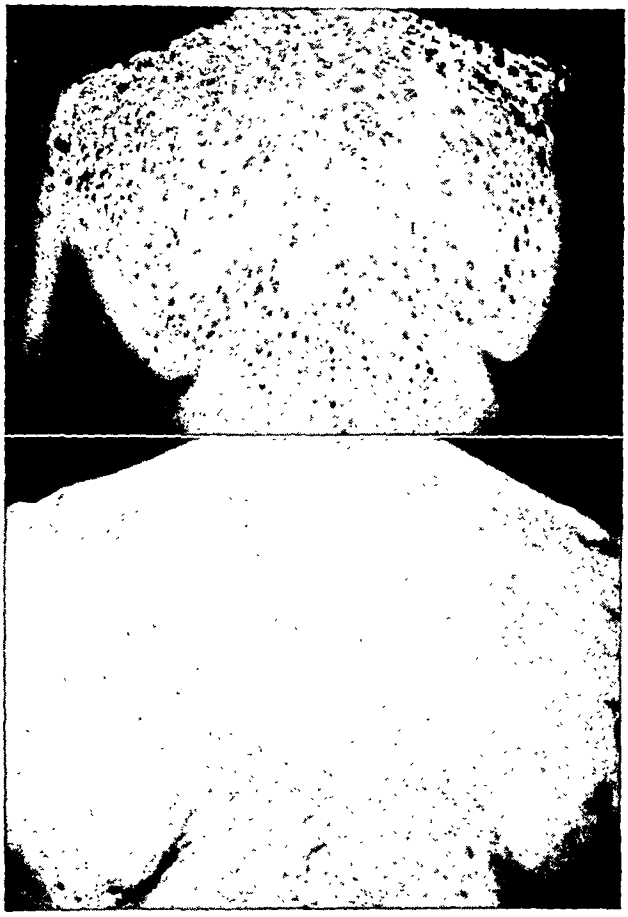

Fig. 1.—The patient, a boy aged 14, had severe, painful cystic acne of the back and the chest of one year's duration. Previous treatment had been with X rays and a low-fat diet. The patient was tired all the time and had an elevation of temperature to 100 to 101 F. each night. For two months he had had a leukocyte count of 18,000 to 22,000. Urinalysis revealed a trace of albumin and an occasional granular cast. He was treated with sulfonamides and penicillin injections with little results but cured by treatment with aureomycin, 2 gm. daily, which he took for four months, and diethylstilbestrol, 0.25 mg. daily, which he took for six months. Cultures grew hemolytic Staphylococcus aureus that was resistant to penicillin and sulfonamides but sensitive to aureomycin. Very little local treatment was given because of the extreme painfulness of the lesions.

Hormone therapy in pustular, cystic, and nodular cases has regularly been prescribed and sometimes is helpful, but on the whole the chief treatment is by administration of terramycin, aureomycin, chloramphenicol (chloromycetin®), or sulfonamides and removal of focal infection.

The importance of sensitization to staphylococci in acne seems corroborated by the recent paper of Hopkins, Weld, and Huber,[2] who by intradermal injections of staphylococci into sensitized rabbits induced histopathologic changes that showed a striking resemblance to cystic acne in the humans. Large purulent cysts, small horn cysts, and comedo-like plugs in hypertrophied hair follicles were seen. There were also acanthosis and hyperkeratosis of the epidermis and downgrowth of the hair follicles.

3. We assume also that the staphylococci in pustular cases of acne differ greatly in their susceptibility to the various antibiotics. This has been repeatedly shown by testing our cultures to penicillin, sulfonamides, streptomycin, and aureomycin as well as by clinical experience. As a rule, penicillin has relatively little clinical effect and the cocci in cultures usually show resistance to it. Sulfadiazine, aureomycin, and terramycin have given us, on the whole, the best results. We have used sulfadiazine in hundreds of cases and terramycin in only about a dozen. There have been a few exceptional cases that failed to respond to any remedy except aureomycin, or sulfapyridine, or dihydrostreptomycin, or terramycin. Very careful cultural studies of such cases failed to demonstrate any Actinomycetes or organisms other than staphylococci.

The deeply nodular and the cystic types of cases were at one time thought to be largely foreign-body reactions about inspissated comedones, but the response of these cases to treatment with the antibiotics pretty well establishes that these nodular and cystic types are due to low-grade infection. Cultures usually grow staphylococci. There is sometimes leukocytosis in such cases that persists until the skin disease is cured. Take, for instance, the following unusual cases:

Case 1.—J. A., 14 yr. of age, consulted us in December, 1948, because of blackheads, tender nodules, and crusted cystic lesions on the face, back, and chest. A complete physical examination by his family physician showed only hyaline and granular casts and pus cells in the urine. Our examination showed, besides the severe cystic acne, a leukocyte count of 24,000 with 75% polymorphonuclear cells, 22% lymphocytes, and 3% eosinophils.

---

[2] Hopkins, J. G.; Weld, J. T., and Huber, W. M.: Intradermal Injection of Staphylococci, J. Invest. Dermat., to be published.

The patient's mother was instructed to take his temperature, and it was found to be elevated each evening. The erythrocyte sedimentation rate was normal. The patient was given daily injections of penicillin, 600,000 units intramuscularly, and aureomycin capsules, 500 mg. four times daily. Sulfonamides were avoided. Improvement occurred but was slow. The urinary findings persisted, as did the leukocytosis and the evening rise of temperature. Cultures from the lesions grew only Staphylococcus aureus. When this organism was tested it was found to be resistant to penicillin and very sensitive to aureomycin. The patient was thereafter treated only with aureomycin and acne capsules, the administration of both of which was continued for eight months, although the acne was cleared and the blood count and urine had become normal within five months. He had never received much local treatment because he had refused to let anyone get near his back on account of the pain he suffered from the raw and undermined crusted cystic lesions.

Case 2.—D. M., aged 14, consulted us in February, 1950, because of severe cystic acne of six months' duration. He had lost 17 lb. (7.7 kg.) since the onset. He was unable to sleep because of the very painful lesions and could not eat since movement of the jaws was extremely painful. He had avoided milk, chocolate, and fatty foods. He had received 20 X-ray treatments by another dermatologist before consulting us. Examination revealed large, crusted cystic lesions on the face, chest, and back. Many large comedones were present. Some of the cysts were blood-tinged. There was a leukocyte count of 15,500 one day and one of 19,500 a week later. Urinalysis showed a faint trace of albumin and very few granular casts. The patient was started on treatment with sulfadiazine, 2 gm., and diethylstilbestrol, 0.25 mg., daily, and the improvement was steady, but after six weeks the medication was changed to the administration of terramycin, 1 gm. daily, which cured him. The diethylstilbestrol therapy was continued. The patient refused much local treatment because of the painfulness of the lesions.

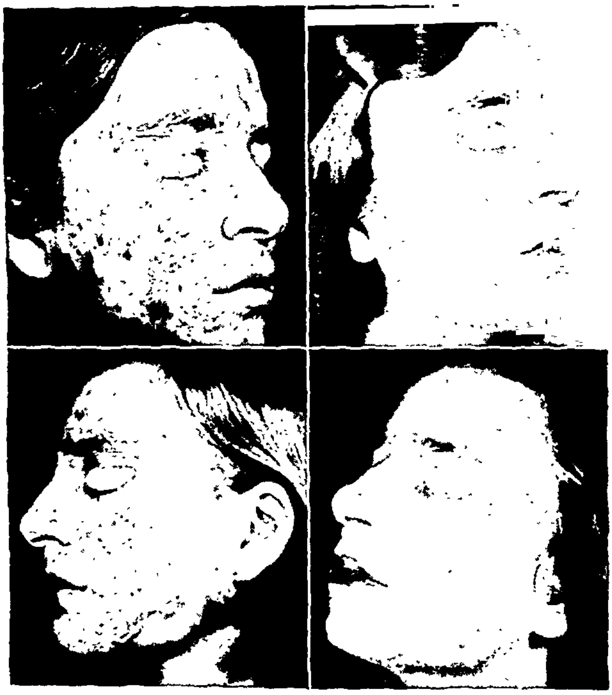

Fig. 2.—The patient, aged 14, had had cystic acne for three years. She had received X-ray treatment, penicillin injections, and a low-fat diet without benefit. Cure was effected by the administration of sulfadiazine internally for four months, tonsillectomy, and the administration of diethylstilbestrol, 0.5 mg. daily. Blood count showed 12,500 leukocytes, 3,900,000 erythrocytes, and 79% hemoglobin at the beginning of treatment. In addition, the patient was given lextron® capsules (a proprietary liver-stomach concentrate with iron and vitamin B complex) and weekly intramuscular injections of estradiol benzoate (progynon® B), 2,000 to 6,000 units, for three months.

FEMALE SEX HORMONE

Female sex hormone has been administered in three ways. First, diethylstilbestrol has been prescribed in an enteric-coated tablet (Eli Lilly & Co., Indianapolis) in a single dose of 0.25 mg. daily. Rarely, the dose was changed to 0.1 or 0.5 mg. On other occasions we have prescribed gelatin acne capsules, each having the following formula:

Diethylstilbestrol	0.00025 gm.
Powdered extract of cascara sagrada.	0.01600 gm.
Desiccated thyroid..............	0.00800 gm.
Sodium bicarbonate, as much as desired	

The patients, male or female, take one at bedtime. Rarely, girls have been given two and three daily. In some recalcitrant cases additional doses of estradiol benzoate, consisting of 2,000 and 6,000 rat units weekly, have been given parenterally.

Fig. 3.—The patient, aged 16, had had pustular acne of the face and the back for two years, during which he was treated by a local dermatologist. He was cured by the administration of sulfapyridine, 2 gm. daily for three months, and diethylstilbestrol, 0.25 mg. daily for nine months. He used lotio alba locally. He had been drinking 3 qt. (2.83 l.) of milk a day; this amount was reduced to a glass a day.

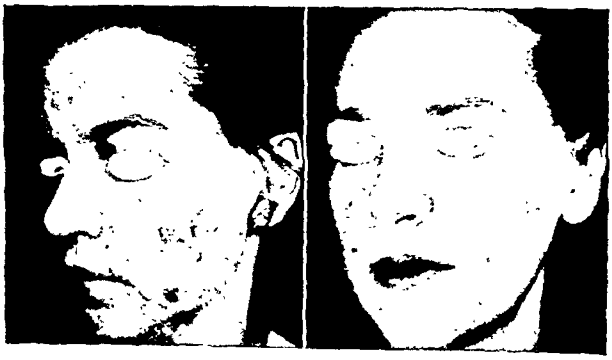

Fig. 4.—The patient, aged 31, had had acne for six years and had received the limit of X-ray treatment and a low-fat diet. The condition was cured by the administration of diethylstilbestrol, 0.5 mg. daily, and sulfapyridine, 2 gm. daily for four months, supplemented by occasional injections of crude liver extract and estradiol benzoate.

In most instances the estrogenic hormone was given throughout the menstrual cycle. In those cases in which previously regular menses became irregular it was necessary to adjust the dose around the time of the menstrual period. This was accomplished in two ways. First, a large parenteral dose of estradiol benzoate (10,000 rat units) was given just before the expected time of the menstrual period, or a dose of 20-25 mg. of progesterone was given in anticipation of menstruation, treatment then ceasing for a time. Apparently after a high level of either estrogen or progesterone has been built up, the ensuing precipitous fall in hormone level accompanying the cessation of treatment with the substance brings about menstruation. The appearance of menstruation is more consistent following progesterone withdrawal. This observation bears out the statement of Grollman [3] that, physiologically, menstruation results from regression of the corpus luteum and a fall in progesterone level in the organism. More recently these schedules have been combined in the giving of estrogen for 16 to 18 days following menstruation, then the substitution of an oral progesterone preparation for five days, and then the withholding of all hormone therapy until menstruation occurs.

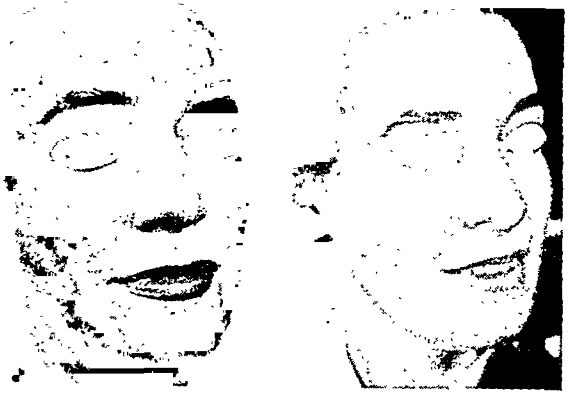

Fig. 5.—Nodular cystic acne in the 30-yr.-old patient was of 15 years' duration. There had been X-ray treatment and dietary restriction. The condition was made worse by the administration of any form of sex hormone and was recalcitrant to sulfonamide, penicillin, and aureomycin therapy, but was cured beautifully and promptly by the administration of terramycin, 2 gm. daily for one month, followed by the use of 250 mg. daily for two months.

Under such a regimen the menstrual periods are usually prompt, occurring 28 to 30 days apart. Similar regulation can be obtained by the administration of estrogen merely during the first two weeks following menstruation, but this method has a drawback in that with it hormone therapy is only at work half the time.

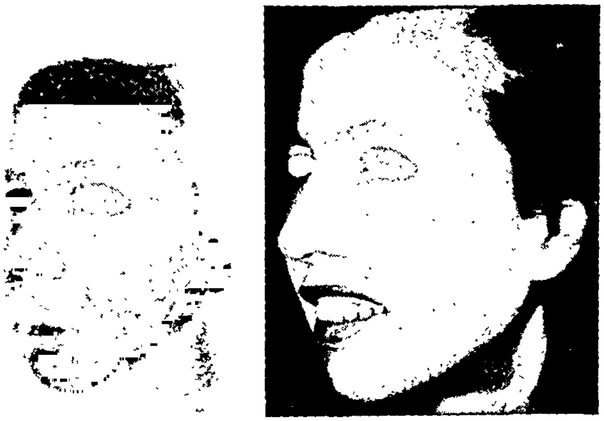

Fig. 6.—The patient, aged 19, had had pustular acne for six years. Previous treatment had been with X rays and diet. The tonsils had been removed. There were unerupted, impacted, infected wisdom teeth. Hemoglobin was 68%. The condition was cured by the administration of sulfadiazine, 2 gm., and diethylstilbestrol, 0.25 mg. daily, and the extraction of the third molars. The patient took sulfadiazine for three months.

With regard to possible untoward effects of female-sex-hormone administration, we should like to quote Wright,[4] who says,

> A dose of 0.25 mg. stilbestrol daily is a minimal one and is right on the threshold of producing possible definite therapeutic effects from the endocrine standpoint.
>
> With respect to the girls, there is probably less likelihood of any possible harm than in the boys. There may be some increase in mammary development and precocious menstruation. This would be difficult to differentiate from that which would normally be taking place in the female at this age. If the therapy is long continued, there might be some interference with normal progression of adolescence.
>
> With respect to the boys, there may be some delay in puberty in a few cases caused by this minimal dose. I would watch particularly for sensitivity to stilbestrol, as evidenced by mammary development in these boys. There may be some depression of testicular function (which would account for the delay in puberty); this would be evidenced by oligospermia but clinically would be rather difficult to determine, since a normal sperm count has never been obtained in these boys.

Wright goes on to say that this form of therapy should not be continued any longer than necessary to control the acne, that total stoppages of diethylstilbestrol therapy at intervals would help prevent untoward effects, and that there is little likelihood of producing permanent definite harm from a dose of 0.25 mg. daily. This statement represents a considered opinion and is a composite view held by several outstanding pediatricians and endocrinologists.

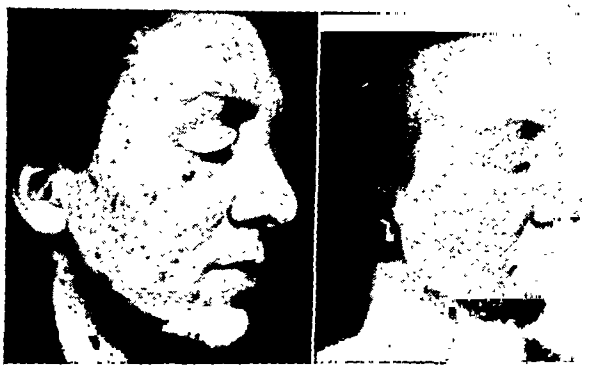

Fig. 7.—The patient, aged 21, had had nodular cystic acne of the face and the back for eight years. She had had 16 X-ray treatments and a low-fat diet. She had two dead teeth. Her acne was worse at menstrual periods, of regular occurrence. The condition was cured by the administration of sulfadiazine, 2 gm., and diethylstilbestrol, 0.25 mg. daily, and the extraction of abscessed teeth. The patient also received crude liver extract, 2 cc. intramuscularly, each week, and occasional injections, 2,000 units, of estradiol benzoate. She took sulfadiazine for six months.

Menstrual disturbances occurred in 65 (25%) of the 262 female patients. This was manifested by delayed menstruation, which was readily corrected by the methods previously noted. In the female patients there was one case of unilateral enlargement of the breasts, which disappeared within two weeks after cessation of therapy. In the 79 male patients there were six cases in which there occurred temporary tenderness or enlargement of the breasts, which was usually not noticed by the patient until it was brought to his attention. One patient took 0.5 mg. of diethylstilbestrol daily from June to October, 1949. His wife recently had a 9 lb. (4,082 gm.) baby boy. Some of the young men who had severe oiliness and acne, so that their appearance was repugnant, took this dose of diethylstilbestrol for two years with nothing but apparent good effects on their growth, on their development, and on their skin. However, to be extra-cautious, we usually try to have rest intervals for the male patients, even if clinically such rest intervals seem unnecessary. In severe nodular, pustular, and cystic types of acne we have not increased the doses of estrogens but have depended largely on the administration of antibiotics. In two cases of the cystic type, any kind of hormonal therapy, even minute doses, made the patients worse. These two patients were cured by use of terramycin.

---

[3] Grollman, A.: Essentials of Endocrinology, ed. 2, Philadelphia, J. B. Lippincott Company, 1947.

[4] Wright, A. (Schering Corporation, Bloomfield, N. J.): Personal communication to the authors.

We gave 341 patients (88%) some form of estrogenic therapy. A group of 154 patients received treatment by estrogens for three months or less, 66 for four to six months, 78 for six to 12 mo. and 42 for 13 to 24 mo. Of these, there were 79 (23%) male patients and 262 (77%) female patients, a ratio of 1:3.4.

SULFONAMIDES AND ANTIBIOTICS

Patients having a very pustular eruption require, in addition to the administration of hormones, a course of sulfonamide or antibiotic therapy. It is important to prevent pustules because scars are mostly caused by pustules. Sulfadiazine is usually given in doses of 2.0 gm. daily for about two weeks, and then the dose is reduced to 1.0 or 1.5 gm. daily for eight or 10 more weeks. Although most pustular eruptions respond to this treatment, some cystic cases do better with sulfapyridine therapy. Blood counts and urinalysis are done frequently while sulfonamides are given. In a few cases of cystic acne aureomycin, terramycin, and dihydrostreptomycin have proved curative when the sulfonamides have failed. Aureomycin and terramycin were given in doses of 1 gm. daily for several months. The use of terramycin has been especially beneficial and well-tolerated. As its cost is reduced, it may become an increasingly valuable remedy in severe pustular types of acne.

It has been brought out in this series of cases that cures of many severe nodular and cystic cases of acne can be accomplished by the use of sulfadiazine, sulfapyridine, aureomycin, or terramycin without any other remedy. This fact alone suggests, first, that we must revise some of the long-held theories about acne, and, second, that infection by staphylococci is the chief cause in some cases.

FOCAL INFECTION

Frequently occurring at an age when acne appears are focal infections in impacted and unerupted wisdom teeth and in tonsils. Especially in patients 19 yr. of age or over, the wisdom teeth should be carefully X-rayed and examined. In older patients, nonvital teeth should be held under suspicion. Rarely other foci, as have been mentioned, are of importance. Many cures of long-standing acne in this series can be attributed to careful search for and removal of foci of infection. Of the 384 patients in the present series, a foci of infection was found in 45 (11%). Of these, the teeth were involved in 29 (64%), the tonsils in 13 (28%), and the sinuses in three (8%) of the cases.

SYSTEMIC MEASURES

Always a complete blood count was done and deficiencies in erythrocytes or hemoglobin were appropriately treated, or leukocytosis suggested further studies for foci of infection or treatment by antibiotics.

The chief features of the diet recommended are the avoidance of excessive amounts of fatty and fried foods and sweets and the eating of plenty of fruit, cereal, meat, and vegetables. Chocolate, nuts, ice cream, cream, egg yolk, and cheese should be avoided. Milk should be limited to a glass or two a day. Diet plays a negligible role in pustular and cystic cases. Where the patient is underweight, has poor posture, pallor, and listlessness, injections of crude-liver extract or vitamin B_{12} are given. These are also useful if there is much seborrheic dermatitis concomitant with the acne. Hypochromic anemia is treated by administration of ferrous sulfate. Arsenic in the form of potassium arsenite (Fowler's) solution was sometimes prescribed. Basal metabolic rates and serum cholesterol levels were determined for many patients, and thyroid extract was given whenever indicated. Staphylococcus ambotoxoid injections were occasionally given in a series of 10 or more injections. In the presence of many comedones, vitamin A is given. The dose ranges from 100,000 to 200,000 units a day, and this dose must be continued for three to six months before its effectiveness may be judged. In addition, aqueous dispersions of vitamin A may be given once or twice weekly parenterally in severe cases of comedones. Such large doses may be continued for months without harm, but prudence suggests that reductions in the dose should be made after a year.

Emotional factors are extremely important in acne. The psychosomatic relationship is unquestionably present, and after the emotional conflicts and problems are rationalized the acne subsides. Observation of the close relation of acne to puberty and sex hormones and the effects of these forces upon the emotions clarifies to an extent the psychosomatic features of acne. We have thought that we noted improvement of the psyche along with improvement of the skin. Perhaps some severe cases of acne are caused by overactivity of the androgens, which overactivity at the same time produces perplexing problems and emotional conflicts for the boy or girl. At any rate, there is no doubt that as the acne subsides from the use of diethylstilbestrol and other remedies the patient becomes happier, more contented and less detached from society.

LOCAL TREATMENT

Local treatment is of great importance. Supplementary cleansing of the skin with alcohol in addition to the use of soap and water morning, noon, and night will decrease the number of comedones and the amount of infection. As a more-or-less routine procedure, we prescribe the application of hot sulfurated lime solution compresses twice weekly and lotio alba or some other sulfur preparation, sometimes containing resorcinol, at bedtime. Occasionally a suspension of ammoniated mercury (alulotion,[5] ammoniated mercury with kaolin, Wyeth, a lotion containing ammoniated mercury, 5%, with kaolin and aluminum hydroxide gel) is used. The application of topical preparations of tyrothricin, bacitracin, and aureomycin is sometimes beneficial. Comedones are extracted and pustules are drained at weekly office visits. Patients are weighed every three weeks. Instructions are given for the patient to wash the face with soap and water at least twice a day and to avoid creams and greasy preparations. Nongreasy cosmetics are permitted but must be applied with clean cotton because reinfection may occur from dirty powder puffs. When peeling of scars is desired, ultraviolet or cold quartz light irradiation or applications of carbon dioxide slush are given, or scarification is done with a No. 11 Bard-Parker knife.

Concomitant seborrhea of the scalp is treated with appropriate local remedies.

CONTROL SERIES

As a control, 1,287 records of cases of acne treated by X rays prior to 1948 were reviewed, and selection was made of 253 of these records which met the following criteria:

1. All patients had been treated with X rays in a period before our newer methods were instituted and had not received estrogenic hormone, chemotherapeutic, or antibiotic therapy. Cases were not included if the patients had received X-ray treatment elsewhere, and a therapeutic total dose must have been given under our supervision. No patient in this series received less than 600 r to the sides of the face, and none received more than 1,400 r to the sides of the face. In some instances, smaller doses were given to the chin or midface in addition to treatment to the sides of the face, a technic no longer used. The average total dose to the sides of the face was 1,050 r. These doses would not now be considered conservative.
2. Each case must have been followed for at least one year after treatment was begun, but in most instances the follow-up period was longer than one year and, in many cases, over five years. The average period of observation for the 253 patients was 35.8 mo., almost three years.

In this control series there were 73 male patients (29%) and 180 female patients (69%), for a ratio of 1:2.46. The average age was 20.17 yr.; the mean was 19.

The results show that 152 patients (60%) were entirely cleared up or improved; 51 patients (20%) were not appreciably better or worse, and another 50 patients (20%) cleared up for a time and then had recurrences. No consistent cause for the recurrences, such as age, sex, or amount of X-ray treatment given, can be discovered in our results. In retrospect, it seems probable that many failures and recurrences were caused by foci of infection in the teeth or tonsils which were given less consideration then than at present or by a continuation of a hormone imbalance in spite of diminished oil-gland secretion brought about by X-ray treatment.

These results are similar to those reported previously by other observers, and discrepancies can probably be accounted for by the mode of selection and the length of the follow-up period.

While it is true that some patients were cured during the first few months of treatment and their cases are not included in the results because they were not observed for a year, these cases are probably balanced off by an almost equal number in which the patients had recurrences during the first year but did not return for further treatment.

RESULTS OF TREATMENT IN PRESENT SERIES

Any critical appraisal of newer methods depended upon discontinuation of routine X-ray treatment. Moreover, an ideal control situation presented itself in those cases in which the safe limits of X-ray therapy had been administered previously. Of the 384 patients in this series, 175 (46%) had received previous X-ray treatment, mostly from other dermatologists.

The final results of treatment in the present series of 384 patients are as follows: 90 patients (23%) were cured; 276 (71%) were improved, and 18 (6%) were unimproved or worse. In other words, 94% were either entirely cleared up or improved. The time of observation has been too short for the number of recurrences to be estimated.

It can be readily seen that these results are superior to those obtained in the control series treated with X rays but without antibiotics and estrogens.

COMMENTS

Statistics in such matters are open to so much personal influence and to so many errors in judgment that probably not too much dependence should be placed on these. However, we who have done this work can assure you that the results have pleased us to a degree beyond expectation. It would be regrettable if estrogenic-hormone therapy were widely used as the sole treatment of acne. A few years ago the view was widely held that acne should be treated solely by X rays without even the expression of any comedones. Both of these views show complete ignorance. Acne is a complicated disease with important medical as well as cutaneous features. Many internal, as well as local, procedures of treatment must be carefully employed in order for one to treat acne efficiently. X-ray treatment in small doses has a permanent place in the treatment of acne. Our experiment is over, and we may use X-ray therapy again occasionally. However, the overwhelming success we have had with modern remedies has dulled our desire to use X rays and has whetted our interest in the modern therapeutic approach to acne.

115 E. 61st St. (21).

ABSTRACT OF DISCUSSION

Dr. Merlin T. Maynard, San Jose, Calif.: In 1933 I largely abandoned the use of X rays in the treatment of acne, and now, 17 yr. later, I have no regrets. Acne responds to certain influences, all of which in a measure tend to do the same thing—that is, influence the amount of ionized calcium in the skin. They are the use of estrogenic hormone substances, calcium injections, the injection of anterior-pituitary substance, ultraviolet irradiation, X-ray treatment, the giving of calciferol or irradiated ergosterol in the presence of a source of calcium. Conversely, acne flares in the premenstrual phase in women when the calcium blood level falls. It gets worse in fevers and wasting illness, when calcium is, likewise, lost. It begins in adolescence, when the demands for calcium by the growing body are greatest. My approach for many years has been through calciferol as a mainstay of treatment. Successful acne treatment swings on a common hinge. Calciferol, synthetic oleovitamin D, and the estrogenic hormones are all steroids. I approve the use of estrogenic hormones in young girls but am inclined to withhold judgment on their use for boys on the ground that the production of feminizing changes, when such boys are most sensitive to their masculinity, is psychologically dangerous. I also question the advisability of delaying puberty. Diet is moderately important, and I agree with the authors, permitting more milk than they do. I insist that gum chewing must be avoided because of the stimulation of the circumoral sebaceous glands and because of the continued movement of the inflamed areas. For local treatment I prefer soluthricin® solution (a solubilized form of tyrothricin, 0.5 mg. per cubic centimeter) in the superficial pustular cases and a solution of the intraderm® type for the usual run of the comedo and deeper forms of the disease. Vitamin A has been disappointing, as I cannot improve on the results in my original series, in which only 50% of my patients showed improvement with the use of this substance. I do not incise pustules, as I find this procedure increases scarring. I prefer to aspirate large lesions with a syringe and needle instead. There is no substitute for the "clinical sense" of the skilful and experienced practitioner in whose hands a treatment is successful that does not prove to be so in the hands of his fellows. We see the failures and not the cures and unfortunately weigh the value of a new regimen of case management on the basis of what is often the minor factor. I feel that all of us will attack the acne problem with new vigor after hearing this stimulating paper.

Dr. William H. Goeckerman, Los Angeles: The authors have made a great contribution to the management of some of these severe cases of acne. The cases presented here probably had a secondary pyogenic infection; the multiple attack is sufficient evidence of that. I wondered whether the authors had any evidence as to what part the estrogens played in the results they obtained. I have been interested in hormone therapy of acne as long as I can remember. My investigative work with estrogens has been restricted to the female. Today I unhesitatingly give the patient with acne a good prognosis, no matter what treatment has been given. I am talking about the patients I have investigated, not so much the type presented here. If my experience can be a guide, in about 30 to 40% of the cases one can obtain a good response by giving the ordinary doses of various types of estrogen. I have used possibly a half-dozen different types while trying to evaluate them. But there comes a time when the acne may grow somewhat worse or makes no progress toward cure, and that is the time when considerable critical judgment must be used. Shall the dose be increased? With perseverance and cooperation of the patients I have had good results in 90 to 95% of my cases. Why is it that certain dosages will produce a good response in some cases and then the benefit will stop, with no further result unless there is modification of approach? There is much clinical and experimental work to support a certain concept with regard to the therapeutic administration of hormones. All hormones probably have an indirect effect, and I think that statement is true of pituitary adrenocorticotropic hormone and cortisone, as well as the estrogens. They work on certain target organs. One can easily overstimulate, as well as understimulate, these target organs. I think hormone therapy is a potent agent in our hands. It can easily be abused. One can, in a certain percentage of situations, give the standard dose as it is usually given, but he cannot say, "This is the dose indicated," because one has strictly to individualize his patients; from this interest in the individual patient one will get excellent results.

Dr. George Kulchar, San Francisco: My only point in rising to speak is to ask questions. Has there been any effect through the use of estrogens in alcoholic solution on the treatment of acne, both on the scalp (acne miliaria type) and on the skin (acne vulgaris)? I have used this preparation and have been impressed with the results, particularly with acne miliaria on the scalp in seborrheic persons. The British are ahead of us to a certain extent in the treatment of seborrheic dermatitis, which is a part of acne, particularly in their use of the estrogens in the treatment of premenopausal women, women 38 and 40, with seborrheic dermatitis, which in this age group is quite refractory to treatment. I wish to ask Dr. Andrews regarding the use of combinations of Staphylococcus antitoxin and vaccine or autogenous vaccines and Staphylococcus vaccines as an adjunct in the treatment of acne.

Dr. George C. Andrews, New York: Of course, the estrogenic hormone increases calcium metabolism, and that fact may be one of the reasons its use is so effective in acne. In regard to Dr. Goeckerman's question, we have used estrogenic hormones in practically all these cases, but we find that, in the nodular cases—and in the pustular cases—we need something in addition to estrogenic hormones. Hormones are not usually sufficient in themselves. They do a great deal of good usually, but, in addition, one has to get after the pustular element, get rid of any focal infection, or treat the skin with antibiotics. We have used estrogens locally but not in alcoholic solution. We used them in ointments, mostly, following the suggestions in a Portuguese article published about a year ago which reported excellent results from the local use of estrogenic ointments. We have not obtained the results the Portuguese workers did. The result, if any, from this treatment is obtained very slowly. We have used vaccines, but the treatment I have described is so clean-cut, so definite, and so short that vaccines are not required; if treatment including the use of terramycin and these other things is followed out, they really are not needed. If there is a focus of infection, it is better to get rid of it than to treat it with vaccine. In most of these cases, the skin is sensitized either by the infection of the skin itself or by some focus to the Staphylococcus.

TREATMENT OF PSORIASIS WITH UNDECYLENIC ACID BY MOUTH

Herbert Rattner, M.D., Chicago
and
Harold Rodin, M.D., South Bend, Ind.

The clinical course of psoriasis has been recognized and described since the time of Celsus, but the cause of the disease still remains unknown. Psoriasis has been attributed to faulty metabolism of both proteins and fats, to parasitic and bacterial infections, to neurogenic disorders, to vitamin deficiency, and to dysfunction of the endocrine glands. A relationship with the arthritides has long been suspected. All these factors seemingly are unrelated, and treatments directed against them have given variable results. There has been no one drug or individual method of treatment that will cure psoriasis or even afford control of the disease in all cases with any degree of certainty. Because of the frequency with which the disease is encountered and the large problem that it presents, the announcement of a new remedy for psoriasis always arouses interest, and so Perlman's[1] first report on the peroral use of undecylenic acid for the treatment of psoriasis attracted considerable attention. This interest was acute, not only because of the favorable results that he reported but also because the treatment was altogether new, with no basis whatever from previous studies with the drug to suggest a rationale for its use in psoriasis. In fact, the drug was first used perorally by Perlman not for psoriasis but for ringworm of the scalp, a treatment that was suggested by the work of Rothman which explained the rarity of tinea capitis after the onset of puberty. Rothman[2] and his associates had demonstrated that "with the onset of puberty the sebaceous glands of the scalp start to secrete a sebum which contains in higher concentration than before, low boiling saturated fatty acids (of the nature of undecylenic acid) with selective fungistatic and fungicidal action on M. audouini." The treatment with undecylenic acid, incidentally, failed to cure the ringworm of the scalp, but

From Cook County Hospital and the Department of Dermatology, Northwestern University Medical School.

This paper is the second in a "Symposium on Therapy," read before the Section on *Dermatology* and *Syphilology* at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 30, 1950.

[1] *Perlman, H. H.:* Undecylenic Acid Given Orally in Psoriasis and Neurodermatitis, J. A. M. A. **139**: *444-449 (Feb. 12) 1949.*

[2] Rothman, S.; *Smiljanic, A., and Weitkamp, S. W.: Spontaneous* Cure of Tinea Capitis in Puberty, J. *Invest. Dermat.* **8**: *81-98* (Feb.) 1947.

during the course of treatment it was noted that there was a profuse desquamation of the children's scalps, and it was this observation apparently which suggested the use of undecylenic acid for psoriasis.

In February, 1949, Perlman's first report was published. This was a study of a small series of 17 patients with chronic psoriasis who were observed for only a short period. Although he emphasized the preliminary character of the report, there was no mistaking Perlman's enthusiasm over the results that were obtained, and this same note of satisfaction ran through his two subsequent reports.[3] In the last of these he reported on his experience with a group of 100 cases as follows: good results in two-thirds of the cases, great improvement in associated arthropathy, and decided relief of itching in 51%. The reactions that he observed, although frequent, were considered to be bothersome rather than serious. "Concurrent topical therapy affected improvement more quickly but the end results were no better than when undecylenic acid was used alone."

The reports were not without interest and significance, and, as we are always alert for "something new for psoriasis," we undertook to use this method, adopting the same dosages that were recommended by Perlman. It soon became evident that our therapeutic results were in no way comparable with those that he had reported. We found that in our group of 40 cases only one showed any improvement. Then, too, we encountered not only a high incidence of gastrointestinal side-effects but also reactions of a more serious nature. There were three cases in which there was almost immediate exacerbation and spread of the disease. In two of the patients the spread continued unhampered to the development of exfoliative dermatitis, and one of these patients became so severely ill as to require hospitalization for treatment with pituitary adrenocorticotropic hormone. We learned through informal discussions with various members of the Chicago Dermatological Society that they also had failed to duplicate Perlman's results and that they, too, were encountering reactions.

The treatment in the meantime had been mentioned in several health columns in newspapers. General practitioners and persons afflicted with psoriasis began to make inquiries. It seemed important, therefore, for fear of prejudging the method, for us to enlarge our sphere of investigation, and questionnaires were then sent to dermatologists in all parts of the country asking specifically for information regarding the number and types of cases treated, the results, the reactions encountered, and considered opinions of the treatment. The men whose aid was enlisted are all experienced dermatologists acquainted with the vagaries of psoriasis. Most of them are qualified teachers of dermatology, and all of them are men of position in the specialty who are known to have serious judgment and not to be given to answering such questions lightly.

It is of interest to note that nine of the 75 dermatologists in this group had not used the treatment because it lacked a rationale. Forty-two of them reported on its use in 1,106 cases. Each case was observed for a period of at least three months, and each physician reported on from 20 to as many as 130 cases. In fairness to the treatment, it was decided to discard answers to the questionnaire that recorded results in fewer than 15 cases, doses smaller than those originally recommended, or a treatment period of less than 10 weeks. It was learned subsequently that these need not have been discarded because the results recorded for this group were similar in essential details to those for the entire group.

Side effects were recorded by nearly every observer. In general these were unimportant gastrointestinal disturbances—either nausea, vomiting, belching, a fishy taste in the mouth, fullness, diarrhea, or "heartburn." They were common symptoms and not unexpected, since undecylenic acid is related to castor oil. It is an 11-carbon, straight-chain unsaturated fatty acid, $CH_2CH(CH_2)_8COOH$, produced by splitting from the ricinoleic acid of castor oil by pyrolysis.[4] It has an objectionable fatty odor and an acrid taste. The symptoms produced by it were unpleasant and bothersome, but in most cases they could be controlled by lowering of the dose of the drug, by the discontinuation of treatment for a while, by a change to enteric-coated capsules, or by the administration of sodium bicarbonate, peppermint, or carbonated beverages. There were recorded also one instance each of headache, conjunctivitis, axillary adenitis, folliculitis, and acneform eruption. There were three cases of urticaria.

Not all of the side effects, however, could be considered inconsequential. In one instance a quiescent peptic ulcer was activated into serious hemorrhage, and in another there was exacerbation of a case of gout which had been quiescent. Recorded also were one case of auricular fibrillation and one of coronary pain, both of which disappeared when the use of the drug was discontinued and recurred when it was administered again. There were 11 cases recorded in which the psoriasis began to spread, not in the manner of a Herxheimer reaction but rather in that of a true exacerbation of the disease, the spread continuing in seven cases to the development of exfoliative dermatitis. The latter must always be considered a dangerous disease, involving as it does the reticuloendothelial system. These reactions, although serious, were nevertheless low in incidence, and their rare occurrence would ordinarily not hamper the use of the drug if the therapeutic results from it warranted its use.

Unfortunately, most of the observers found their results disappointing. Despite an occasional favorable response to the treatment, eight men recorded their

results as inconclusive, and four, although their results proved disappointing, felt the method should have a longer period of trial. The overwhelming opinion, however, from 38 of the physicians, was strongly critical of the treatment. They expressed their judgments in terms such as "absolutely worthless," "dangerous as well as worthless," "totally unimpressed," "decidedly ineffective," "very disappointing," "no longer use it," and "cannot recommend it." These comments are cited only because they are so emphatic. New drugs, new methods of treatment, or new interpretations of disease usually are met with some reservations, and differences of opinion are often freely expressed, but seldom are opinions stated with such vehemence as were those which have been cited. The significance of this fact is obvious.

At the meeting of the American Academy of Dermatology and Syphilology in December, 1949, these results were discussed before the section on pharmaceutical therapeutics and before the popular "Stump the Experts" panel, which was attended by some 500 members. The fact that more than half of the queries submitted to the panel dealt with the treatment of psoriasis with undecylenic acid gives some indication of the widespread interest in it. When Dr. Perlman rose to refute the results recorded on the questionnaires, his spirited defense of his treatment was received rather unsympathetically by the audience. But, of greater importance, he received open support from only one other physician, whose experience, as he himself pointed out, was limited to but eight cases. A few others "were not yet willing to condemn the treatment." In sharp contrast, the general tone of the comments heard at these sessions and informally through the several days of the meeting was unmistakably in agreement with those reported in the questionnaires, both in substance and in emphasis of expression. One observer told of a case of labyrinthitis [5] that resulted from the use of udecylenic acid; there were several reports of drug eruptions, reports of two instances of nephritis, and mention of quite a few additional cases wherein exacerbation occurred, sometimes to the development of exfoliative dermatitis.

COMMENT

Psoriasis is an erratic disease. Its course is not always one of relentless progression. It is capable of spontaneous exacerbations and remissions, and such remissions may last for years. It is often subject to seasonal variations and sometimes to emotional influences. It is a common observation that in some persons psoriasis will respond to almost any form of therapy and recurrences in the same patients may later resist the same therapy. It has been observed, too, that results from treatment often are directly proportional to the enthusiasm with which the treatment is administered. It would seem, then, that before any therapy can be evaluated for a disease such as psoriasis it must necessarily be tried on many types of cases and for a long period—years may be necessary for proper evaluation of a new treatment. It is easy to err in the direction of undue optimism. Perhaps one may err also in discrediting a treatment too readily. In this instance we think we have not, for we have made it a practice from time to time up to the past few weeks to inquire of our colleagues about their subsequent results from the treatment. Like us, not one has had reason to temper his original unfavorable opinion of it.

Unless experience with pituitary adrenocorticotropic hormone [6] and cortisone—which is only beginning—should prove to be successful, there is still no one method of treatment that will cure the disease or even afford certain control in all cases of psoriasis.

SUMMARY AND CONCLUSIONS

This report on the use of undecylenic acid by mouth for the treatment of psoriasis is based on the experience derived from its use in more than 1,100 cases. Eighty-five of these were treated by us; the others, by some 75 dermatologists from all sections of the country, who, in reply to a questionnaire, recorded results, reactions, and impressions following use of this treatment method. Because the clinical course of psoriasis is so unpredictable and erratic, and because the treatment with undecylenic acid is so new—the first report having appeared less than two years ago—only a status report can be made at this time.

A review of the answers to our questionnaire revealed that side effects occurred frequently. Most of them were unimportant gastrointestinal "upsets," but not a few cases were encountered in which there was a flare-up and spread of the psoriasis even to the development of exfoliative dermatitis. There were several isolated instances of other side reactions, too. Only a few of the physicians regarded their results as at all favorable, while several others were undecided and preferred to defer expression of a final opinion for a time. On the whole, however, the overwhelming opinion was decidedly unfavorable, some of the physicians recording their impressions in terms such as "worthless," "ineffectual," and "disappointing."

General Practitioners and Scientific Exhibits.—The Scientific Exhibit at the meetings of the American Medical Association is administered by a committee of about 30 persons, headed by the Committee on Scientific Exhibit of the Board of Trustees. Each of the sections of the Scientific Assembly elects a representative to the Scientific Exhibit to assist and advise, in addition, there is a general advisory committee. Under such auspices, the best in medicine is shown at American Medical Association sessions, with leading physicians participating. One of the visiting British physicians attending the recent Atlantic City meeting said he was amazed to see how cheerfully the leaders in various branches of medicine make themselves available to the small-town practitioner. Nowhere else in the world is such consultation and advice possible.

BROMIDE INTOXICATION TREATED WITH AMMONIUM CHLORIDE

Theodore Cornbleet, M.D., Chicago

Many physicians believe bromides have fallen into disuse and newer drugs have completely replaced them. This is far from the truth—people take large amounts of these "old-fashioned" remedies continually. Authorities tell us bromides should be discarded, but physicians still prescribe them, and the public obtains them freely and easily in proprietaries and by name "over the counter." The habit that many develop of feeding at the "bromide bottle" can lead to evil effects that all should be aware of. The drug accumulates in the body sometimes to dangerous levels and then, on occasion, disaster results. The reason for dire effects is twofold: Many people keep taking a bromide without a let-up, and it is excreted slowly.

Bromides need not be taken for a very long time, however, or in large doses for evil effects to occur; a few persons seem more easily injured by this drug, and some call this facility "allergy." Large-enough accumulations, however, will harm anyone. People with bromide intoxication may show mental symptoms and at times need to be sent to institutions. Our patients, however, all had cutaneous eruptions, which can be of diverse forms and mimic the rashes of many other diseases. It is common knowledge that bromide eruptions are not uncommonly misdiagnosed. Most of us do not realize to what extent people take drugs (certainly bromides), and even if we should think of asking a patient about them, we accept his denial too easily. Dermatologists appreciate how difficult it is to wheedle a reliable drug history even from patients who are honest and eager to cooperate. After unearthing the fact that the patient's troubles are due to the bromides he has been taking, it is important—at times, lifesaving—for one to know how to displace them quickly.

Blood and Interstitial Fluids
Total halogen level stays constant

Fig. 1.—The proportion of spill-over through the kidneys of any one halide to the others is the same as that in the total mass of blood, tissue, and tissue fluids. The total of chloride is so much greater than that of the other halides that at any one time bromide constitutes a relatively small proportion of the total halide washed out through the kidneys. It takes a long time until all the halides present in the body at any time are finally excreted and replaced.

To do this, we ought to know how the halides behave in the body. This will help us administer these drugs with better effect and less dangerously, too. The body makes little distinction in the handling of either bromide or chloride—it absorbs one as well as the other and distributes them in about the same manner. Their relative concentrations in the interstitial fluids depend on how much of each was ingested or injected and how much was there beforehand. The halides remain for the most part extracellular. Appreciable amounts are in the red cells, although little penetrates other cells. Just as with absorption and distribution, the body shows little distinction in the way it excretes bromides or chlorides. From a physical point of view, one halide will take the place of another.

Halogen filters through glomerulus
Returned to common pool
Diuretic (ammonium chloride) acts as valve or block to reduce resorption of fluids back into common pool
Resorbed from tubules into capillaries

Fig. 2.—Chloride displaces bromide from the blood and tissues. Halides are filtered through the glomeruli but partly reabsorbed through the tubules. Acid diuretic chlorides prevent a part of the reabsorption back into the blood, thus sending more bromide out through the urine and hastening its depletion in the body.

Sollmann [1] says that bromide excretion takes place mostly through the urine but that some bromide gets into the feces. There is a small amount in milk and sweat, and some is present in the exfoliating epidermis. The rate at which bromide is excreted depends on its concentration in the fluids, the amount of other halide taken up to replace it, and the ability of the kidneys. O. Bodansky and Modell [2] found that mersalyl (salyrgan®) and theophylline step up the excretion of bromide and chloride. My associates and I found this, too, provided that the administration of a halide accompanied the giving of the diuretic. When there is no further uptake of bromide, less is excreted—at first, very little less. Later it clings to the body more and more, so that traces of it may remain afterward in the urine for as long as a month and even longer.

Chloride hastens the excretion of bromide by a sort of exchange process. That is why the ingestion of foods that contain little chloride retards the excretion of

bromide. Wagner and Bunbury[3] say that they found higher levels of bromide in the blood when they gave large doses of sodium chloride. They believe that the reason for this observation is that chlorides mobilize bromide from the tissues faster than the kidneys can excrete the latter halide. We did not find this to be so.

The knowledge that chloride will displace bromide from the body led to the use of sodium chloride for this purpose. The administration of sodium chloride by mouth and injection is today the standard treatment for bromide intoxication. It seemed to us that there might be some advantage in having a diuretic accompany the use of chloride for this purpose. Increased formation of urine could perhaps carry off more displaced bromide. One could use the popular mercurial diuretics, but doing so would add another remedy to the primary one (sodium chloride). Besides, there is some risk in using them. The acid diuretic chlorides, such as ammonium chloride, on the other hand, not only provide chloride but are diuretics at the same time. Moreover, they are relatively safe.

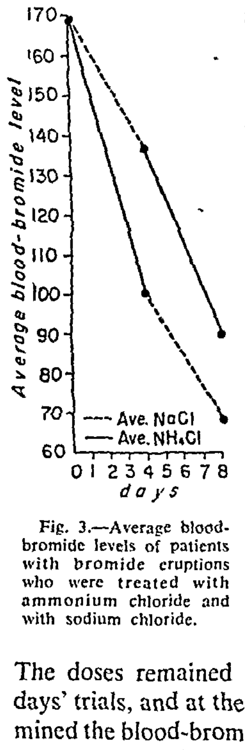

Fig. 3.—Average blood-bromide levels of patients with bromide eruptions who were treated with ammonium chloride and with sodium chloride.

In this study we compared the effects of these diuretic chlorides with those of sodium chloride (the standard for treating bromide intoxication) in a group of patients with bromide eruptions and volunteers who took bromides, to see whether the diuretic agents offered any advantage. We divided the patients into two groups: One received ammonium chloride for the first four days (6 gm. daily in enteric-coated tablets). At the end of four days we determined the blood-bromide levels and then started the second four days' tests. The group that began with ammonium chloride then received sodium chloride, while the one that started with sodium chloride changed to ammonium chloride. The doses remained the same during the second four days' trials, and at the end of this period we again determined the blood-bromide levels. In this way we continued to reverse each patient's and volunteer's treatment every four days until most of the bromide in each was gone. We believe that by arranging the experiments in this way we were able to make fair comparisons as to the relative efficacy of the diuretic chlorides and sodium chloride for removing bromide from the body (Table 1). There were five patients in the first experiment—four with acneform lesions, and the fifth with granlomas on the legs.

METHOD

The method of estimating the blood-bromide levels was the Taylor modification of Wuth's method as described by Todd and Sanford.[4]

Reagents.—Reagents used were as follows: (*a*) a 10% solution of trichloroacetic acid; (*b*) a 0.5% solution of gold chloride in distilled water, and (*c*) standard solution, prepared by the dissolving of 100 mg. of sodium bromide in 20 cc. of distilled water and then the addition of a 10% solution of trichloroacetic acid (*a*) to make 100 cc. One cubic centimeter of this standard solution is the equivalent of 1 mg. of bromide.

Technic.—The following technic was used: 1. Five cubic centimeters of blood was withdrawn by venipuncture and placed in a tube containing ammonium oxalate.

TABLE 1.—*Blood-Bromide Levels (Milligrams) in Subjects with Bromodermas Given Sodium Chloride or Ammonium Chloride in Alternating Periods*

Subjects	Initial Value	4 Days	8 Days	12 Days	16 Days	20 Days

Subject D had granulomatous lesions over the lower legs; the other four had acneform lesions.

2. Two or 3 cc. of oxalated blood was diluted with four times its volume of a 10% solution of trichloroacetic acid (*a*).

3. The mixture was centrifuged and filtered.

4. To 5 cc. of the filtrate, 1 cc. of a 0.5% solution of gold chloride (*b*) was added in a test tube.

5. Two cubic centimeters of the standard solution (*c*) was placed in a tube and trichloroacetic acid added to make 5 cc. Then 1 cc. of a 0.5% solution of gold chloride was added. Solutions were compared in a colorimeter with the standard set at 20.

Calculation.—The following was the calculation used:

$$\frac{20}{\text{reading of unknown}} \times 2 \times 100 = \text{mg. of bromide per 100 cc.}$$

RESULTS

The results of these tests on patients with bromide eruptions seemed to show that their blood-bromide level fell more rapidly when we treated them with ammonium chloride and more slowly with sodium chloride therapy (Figs. 3 and 4).

We made the second study on a group of seven volunteers. Each took 3 gm. of sodium bromide daily for seven days, and then we determined their blood-bromide levels. After this part of the study the seven subjects were divided into two groups—one of three and the other of four. We alternated their treatment

every four days, using diuretic chlorides and sodium chloride in turns, just as we did with the patients with bromide eruptions (Table 2). The results of this study again seemed to show that the blood-bromide levels fell more rapidly with ammonium chloride and less rapidly with sodium chloride (Figs. 5 and 6).

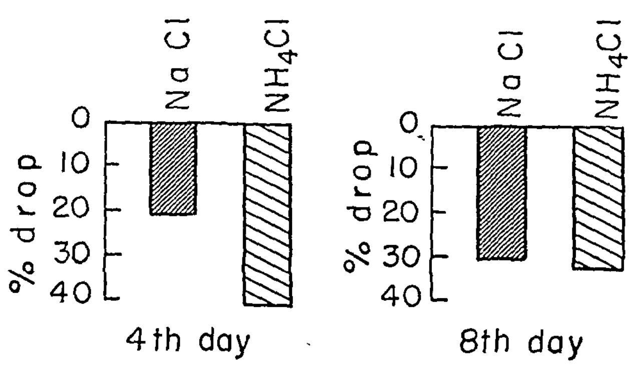

Fig. 4.—Percentages of drop in blood-bromide level observed on the fourth day and on the eighth day of treatment in patients with bromide eruptions treated with ammonium chloride and with sodium chloride.

One volunteer took 3 gm. of sodium bromide daily for two weeks and then received two injections of mersalyl a week apart. As with all the other patients and volunteers, we determined his blood-bromide levels every four days. The mercurial diuretic by itself seemed not to clear the blood of bromide any faster than did ordinary diets in three other volunteers (Tables 3 and 4). Evidently the diuretic needs chloride with it to hasten bromide excretion.

One volunteer took 3 gm. of sodium bromide daily for two weeks. When he finished with this, he drank fruit juice daily containing 60 gm. of urea. The administration of urea did not hasten the loss of bromide from his blood (Table 5). (We used urea because the liver forms it from ammonium, and this observation in itself could conceivably account for the action of ammonium chloride in our studies.) Perhaps we should have used the urea together with a chloride for a more adequate test.

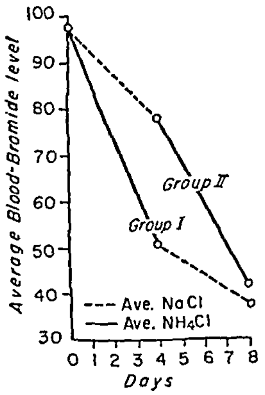

Fig. 5.—Average blood-bromide levels of volunteers treated with ammonium chloride and with sodium chloride.

COMMENTS

The whole purpose of the treatment of bromide intoxication is to hasten the removal of the halide. There are two main steps in doing this: The first is the displacement of the bromide from its combinations, and the second, its excretion. The total level of all the halides together in the blood and intercellular spaces remains at about a fixed level. The injecting or ingestion of chloride forces as much stored, combined halide into the urine. Water lost in dehydrating the body (sweat and urine) carries with it, too, these multiple halides. Obviously, this method alone has its limitations and is, otherwise, objectionable.

Diuretic chlorides have a dual action in removing bromides. They furnish chloride for displacing the bromide and at the same time are diuretics. We believe ammonium chloride is the most advantageous one to use. It is simple, cheap, and fairly safe. It should not be used when the kidneys are damaged. The enteric-coated tablets are not irritating to the stomach, and most people can take a total of 5 to 8 gm. a day in divided doses without distress.

There are several ways to explain the action of the diuretic chlorides in increasing urine formation. According to a modern theory, chloride filters through the kidney glomeruli, but more than 99% of this filtrate is reabsorbed back into the system by way of the kidney tubules. When ammonium chloride, for example, is given as the diuretic, the liver converts the ammonium into urea. There remains then an excess of chloride, and this the tubules refuse to reabsorb from the urinary filtrate. There is a limit to the amount of strong acid the kidneys can excrete, and so some of the chloride is neutralized by sodium or a fixed base. Compensatory factors acting through the posterior lobe of the pituitary body and the adrenal cortex cause an equivalent amount of water to leave with the sodium.

The body can detoxify many drugs by conjugation or other process. In bromide intoxication, however, the offender must be excreted. This fact explains, too, why the untoward actions of this halide may persist. Since more than 99% of the halide filtering through the glomeruli gets back to the blood, the bromide must make many trips to the kidneys before all of it ultimately stays in the urine. This bromide and its larger ratio of chloride together require a long time for removal by this piecemeal excretion process. Another factor that probably acts to retard the loss of bromide is the presence of some of the substance within the red cells. This amount is not filtered directly. As the plasma-bromide level falls, some of the halide in the erythrocytes leaves and is taken up by the fluid pool and is then subject to kidney filtration. This observation probably accounts for an appreciable time lag.

Some kinds of lesions naturally heal more quickly than others. The small acne-like lesions from bromide clear away quickly after the patient stops taking his medicine. The large, fungating granulomas on the legs, however, take much longer to resolve. But, then, most granulomas are torpid, and lesions on the legs take longer to heal than their counterparts elsewhere.

SUMMARY

We made clinical and experimental observations on patients with bromide eruptions and volunteers. The therapeutic abilities of the acid diuretic chlorides (ammonium chloride) and sodium chloride for displacing blood bromide were compared. We found that bromide is excreted and lesions heal faster with ammonium chloride than with sodium chloride treatment. The theory of chloride action in combating bromide intoxication is briefly outlined and discussed.

30 N. Michigan Blvd.

ABSTRACT OF DISCUSSION

Dr. C. P. Bondurant, Oklahoma City: I should like to congratulate Dr. Cornbleet on his fine study of bromide retention. My interest in this subject has been of long standing, and I realize that this type of investigation requires much detailed attention. Since my work on the use of the cortical hormone with reference to bromide excretion, I have seen an increasing number of cases of bromide intoxication. Dr. Cornbleet's point as to who takes bromides is well put. This drug is more widely used than we suppose. Laymen, druggists, and many physicians are still not alert to the dangers of this so-called mild sedative. The warnings and legislation which exist against the barbiturates have driven many to the use of the unrestricted bromides, and when we review the list of commonly used remedies which contain bromides, we are not surprised at the number of bromide-retention cases which are seen. We need legislation regulating the sale of bromides the same as has been enacted for barbiturates. If we can do nothing other than to put that point over to the public in this paper, our efforts will be well spent. It is generally accepted that a blood-bromide level of 150 mg. is necessary for the production of psychotic symptoms, but this high a level is not needed for the dermatological lesions. I am sure all of us have seen flare-ups in these cases with continued use of bromides. The statement that the body must be rid of all its bromide is fundamental in this type of therapy. I cannot quite go along with Dr. Cornbleet on the idea that a blood-bromide level of 22 to 30 mg. is all right. In handling this type of therapy, we must rid the body of its bromides if we are to rid it of its symptoms. A study of the spinal fluid is most interesting. The chemical exchanges in the spinal fluid are slow in comparison with those in the blood and other tissues and account for the prolonged time necessary for recovery in intoxication cases. We might say that the spinal fluid acts as a reservoir and, as its bromides are unloaded into the system, an exacerbation of the condition in the spinal fluid may be caused. One of my colleagues, who is a professor of pharmacology, determined the bromide level on some spinal fluid taken at autopsy and found it to be 400 mg., which observation shows that bromides not only are intoxicating but can produce fatal outcome in these cases. We try to include a spinal-fluid examination in all cases of bromide intoxication, and here I might suggest, as a further treatment of bromide intoxication, and particularly the cases with psychotic symptoms, that repeated spinal drainage is a good procedure. Repeated spinal drainage should have a place in the treatment of all bromide-intoxication cases that have gone to a state where they include any type of mental disturbance. Dr. Cornbleet has shown that the use of a diuretic chloride is superior to the old sodium-chloride method used alone, and he is to be commended on this observation. The addition to this therapy of cortex-hormone will aid these patients considerably. I believe that more work is necessary to determine the proper range of dosage of ammonium chloride in these cases. The use of this type of replacement therapy is not without some dangers. Since many bromide-takers are abnormal otherwise, complete blood-chemistry and kidney-function investigations are necessary. This work establishes clearly the superior therapeutic effect of ammonium chloride over the mercurial diuretics, the latter endangering the chloride reserve. Nature's own diuretic, water, should be used freely, but with due regard to kidney function. Much valuable data could be gained if we extended this study and not only recorded the blood-bromide level but also examined each specimen for sodium, potassium, and chloride content as well.

Dr. Theodore Cornbleet, Chicago: Harris and Derian have called attention to the fact that chronic bromide intoxication presents a syndrome similar to that of pellagra. They gave their patients nicotinamide and obtained gratifying results. They recommend that this vitamin factor be given alone in cases of cardiac decompensation when sodium chloride is contraindicated. Ammonium chloride, too, might be useful in such cases, I believe. Cortisone and other cortical steroids influence sodium and potassium chloride (and, of course, bromide) retention and excretion. They will provide, no doubt, another means to combat bromide intoxications. I think, however, for the present, that the use of ammonium chloride provides us with a simple method for quickly removing bromides from the body.

Writing Medical Papers.—Sir William Osler, although his short intelligible papers in simple English do not show the signs of effort, often rewrote his papers six or eight times in longhand before they were typed for the first time. Sir Clifford Allbutt thought it reasonable to go over a paper about nine times. Tolstoy said, "I cannot understand how anyone can write without rewriting everything over and over again." . . . Dr. William H. Welch told his classes that almost all of the great discoveries in medicine were reported in articles of less than 3,000 words. . . . However, accuracy and clarity should not be sacrificed in an attempt to achieve brevity. You owe your reader a complete explanation.—Miley B. Wesson, Writing a Medical Paper: Why and How, *Journal of Urology*, April, 1951.

ASPHYXIA NEONATORUM

NEW METHOD OF RESUSCITATION

Allan Bloxsom, M.D., Houston, Tex.

The purpose of this study is (*a*) to examine critically the present methods of resuscitation of the asphyxiated newborn infant and (*b*) to present the results of a new method of resuscitation using positive pressures in an oxygen air lock for oxygenation and the expansion of gases to expel pulmonary fluids and secretions.

The material for this study consisted of 100 asphyxiated newborn infants delivered by members of the obstetrical staff of St. Joseph's Maternity Hospital during the period Jan. 4 to May 4, 1950. During this period there were 1,786 deliveries, which gives an incidence of one in every 18 newborn infants requiring resuscitation. In every 100 deliveries approximately six infants were sufficiently asphyxiated to require special resuscitative measures.

Behind the physiological curtain of a considerable degree of cyanosis,[1] consisting of an average mean capillary unsaturation of more than 6.5 vol. % of oxygen in which the fetus exists in utero normally before birth, exists a mechanism that at the start of labor places the fetus under pressure, increases at intervals the oxygenation of the fetal blood,[2] maintains adequate heat and moisture, and provides stimuli to initiate respirations.[3]

The purpose of labor is believed to be twofold. That which is most obvious is the birth of the infant. The hidden purpose is found in the prelabor contractions and resulting pressures leading to respiratory efforts.[4] Pressures generated at labor serve as an important part in the conditioning of the fetus [3] to start his respirations promptly. The final mechanical squeezing of the infant's chest by the birth canal when the head has been delivered, which obstetricians have observed on many occasions, serves in the immediate expulsion of fluids from the pulmonary tree as a concluding step in the preparation for respiration.

The mechanism of this conditioning of the fetus by the mother is believed to be (*a*) a washing in and out of amniotic fluid by a minute tidal wave in an effort to prevent atelectasis at birth by a predelivery expansion of the alveoli in fluid and (*b*) a variation in the pressure gradients of oxygen and carbon dioxide to condition and stimulate the respiratory center. The above chain of events opens the short second act in the newborn infant's life during labor and should be considered the initiation of his "operation oxygenation."

Asphyxia neonatorum results when the events and forces operative to introduce oxygen into the fetus and newborn infant are lacking, or a physiological barrier is produced causing anoxia. Anoxia may be classified generally as anoxic, anemic, stagnant, or histotoxic. Specifically, a few of the clinical conditions resulting in asphyxia neonatorum are narcotization, effects of certain types of anesthetic, prolonged periods of anesthesia, prolonged periods of anoxia resulting from the premature separation of the placenta, prolapsed cord, cord about the infant's neck, lack of labor pressures in cesarean section, and certain toxemias of pregnancy disturbing the pressure gradients of oxygen and carbon dioxide between the mother and the fetus. Eastman [5] found that in the severely asphyxiated infant the oxygen content of the umbilical vein averaged 1.3 vol. % and the carbon dioxide tension 61.6 mm. of mercury.

The immediate problem of relieving the asphyxia neonatorum and resuscitating the handicapped infant resolves itself, therefore, into one of not only getting the respiratory center to function properly in the presence of a severely disturbed blood concentration of oxygen and carbon dioxide, but preventing a damaging anoxia of the cells of the central nervous system until adequate external respiration will provide sufficient oxygenation of the blood for adequate internal respiration.

After a study on the difficulty of beginning respiration seen in a series of cesarean section infants,[3] the thought occurred that the varying positive intrauterine pressures had an essential and important part in oxygenation and preparation of an infant to initiate quickly his respiration, both external and internal after a normal delivery. It seemed reasonable that if a means could be constructed to enable the newborn infant having difficulty in beginning oxygenation and adequate respirations to assume once more the pressure conditions existing in utero during labor and, at the same time, be supplied heat, moisture, and oxygen and exposed to slow, gentle chest respiratory exercises, similar to those he received in utero from changes in pressure, there might be a more favorable outcome, with regard to not only the infant's immediate existence but the future development of his central nervous system. Accordingly, a positive-pressure oxygen air lock [6] was constructed (Fig.) to contain the asphyxiated infant, furnish him with heat, moisture, increased oxygen concentrations for peripheral absorption, and pressures, together with a cycling of those pressures simi-

---

The positive-pressure oxygen air lock was manufactured by the Loewenstern Corporation, Houston, Tex.

The members of the Obstetrical Service and Sister Carmen of St. Joseph's Maternity Hospital helped to make this study possible.

lar as far as possible to those he might receive during the second stage of labor. Table 1 shows the advantages that might be expected from positive-pressure oxygen air resuscitation of the asphyxiated newborn infant.

The first 100 asphyxiated newborn infants oxygenated and resuscitated in an oxygen air lock were in a group of 1,786 deliveries at the St. Joseph's maternity Hospital in Houston, Tex., from Jan. 4 to May 4, 1950. The immediate results of treatment in these 100 asphyxiated newborn infants are shown in Table 2.

TABLE 1.—*Advantages of Positive-Pressure Air Resuscitation of the Asphyxiated Newborn Infant*

1. Promotes bronchial drainage by the expansion of gases for the expression of fluids and secretions in the pulmonary tree
2. Provides a more uniform alveolar aeration
3. Increases absorption of oxygen through the skin and upper respiratory passages
4. Relieves and protects against atelectasis
5. Provides gentle breathing exercise and improves muscle tone
6. Combats acute pulmonary edema
7. Provides favorable conditions for the diffusion and use of oxygen by the premature infant
8. Disposes of handling of infant on part of the physician or nurse

Total	57	43	40	36	17	7

During the four-month period this study was carried out, a total of 34 newborn infants died in this hospital. Ten of the newborn infants who died were not placed in the air lock, either because there was not a lock available or because the physician in charge did not order this method of resuscitation. At first the lock was used in a number of cases as a measure of last resort; the infants were deeply cyanotic many minutes past the time of delivery, and the irreversible changes described by Schmidt [7] had occurred in numerous instances. One of the infants was to all purposes dead, and no heart beat could be elicited when it was placed in the lock. Heart beats and respiration, of course, could not be established.

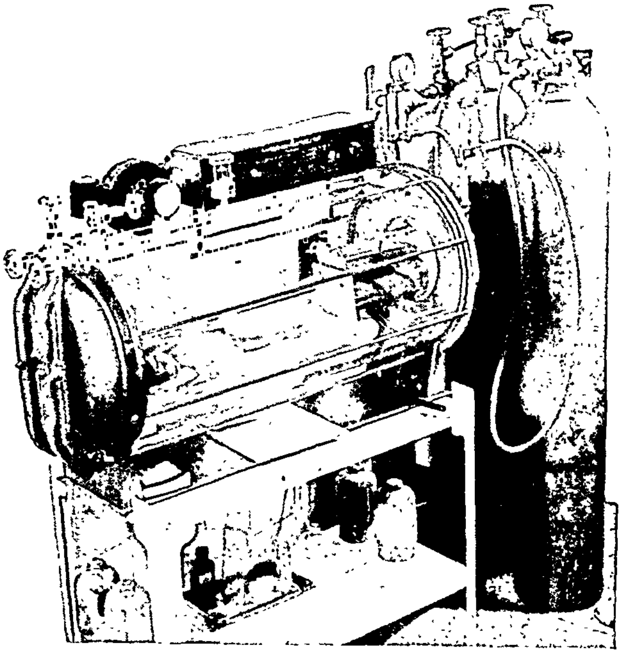
* *L.* indicates living and *D.* dead.

The mortality rates of the first four months of 1949, when the air lock was not used, and the first four months of 1950, when it was in use for the obstetricians who desired it in the St. Joseph's Maternity Hospital, are given in Table 3. The associated decrease of 25% in the death rate of the living newborn infants since the oxygen air lock was first used has to be examined for other possible favorable factors operative to reduce the death rate in any hospital. One major factor is the decrease in the number of premature infants delivered. During the first four months of 1950 the incidence of premature deliveries dropped to 5.15 from 5.95% in 1949. This decrease would account for some of the favorable decrease in the infant mortality rate, provided the premature birth weights were in both years comparable. However, the incidence of very small premature infants delivered weighing 1,000 gm. or less increased about 50% in 1950 as compared with 1949. A very high percentage, about 85%, of the premature infants weighing 1,000 gm. or under die. The reduction in premature delivery rate that favorably influences the infant mortality rate has been neutralized to some extent or done away with by the great increase in deliveries of premature infants weighing 1,000 gm. or less. It is believed, therefore, that there has been an actual decrease in the death rate of the newborn infants in this hospital associated with the use of the positive-pressure oxygen air lock.



Positive-pressure air lock.

Table 4 shows the time required by the 100 asphyxiated newborn infants in the air lock. It is interesting to note that all premature infants living more than 24 hr. survived. The great majority of deaths of premature infants occurred 2 to 4 hr. after delivery. The majority of the full term infants died 12 to 24 hr. after delivery. Once a premature infant reached the 24-hr. mark he required four to 10 days to establish adequate oxygenation and respirations. One edematous infant was left in the lock for 80 hr. before administration of fluids was considered advisable. Several premature infants were left in the lock 48 hr. until the skin appeared nonedematous.

COMMENT

Henderson [8] states:

> The first quarter of an hour after birth is the most dangerous period of life. Its mortality is as great as that of any subsequent month. No single discovery in medical science or improvement in practice could do more to save lives than would measures to avoid the losses that now occur within a few minutes after birth.

Eastman [5] insists that "there seems to be only one urgent indication in the treatment of asphyxia neonatorum, and that is to introduce oxygen into the circulating blood of the infant." In addition, it seems to me that a number of the asphyxiated infants are in considerable shock, cold and listless, with all the tissues of the body in poor tone. The correction or prevention of further increase in shock, the increase of the infant's blood pressure, and the increase in tissue turgor, are all quite necessary, in addition to the introduction of oxygen into the asphyxiated newborn infant.

TABLE 5.—*Results of Use of Expansion of Gases to Remove Pulmonary Fluids and Secretions in One Hundred Asphyxiated Infants*

Total	10	9	3	1

The relieving of the anorexia of the asphyxiated infant can be considered the infant's "operation oxygenation" and appears to take place easier when there is a positive pressure to increase the rate of diffusion of the oxygen and carbon dioxide molecules. These pressures in the air lock have been made to correspond roughly to the relative intrauterine pressures found by Salerno.[9] The lack of a variation of these positive intrauterine pressures in infants delivered by cesarean section has resulted in an increase in difficulty in beginning respiration of approximately 25%.[3] Prelabor contractions were observed by Windle [2] to be accompanied with an improvement in the color of the umbilical vein. The frequent slowing down of the fetal heart beat at the height of labor contractions in the early part of the labor probably indicates a hyperoxygenation of the fetus. The subsequent increase of rate with the relaxation of the uterine contraction means once more a state of relative anoxia. Toward the end of labor, when the pressures are such that the uterine arteries and veins are embarrassed, the above conditions are probably reversed.

With the condition of shock in which these infants often appear to be, it seems logical that the stagnation of the blood in their lungs makes it more difficult to absorb oxygen and give up carbon dioxide. It may well be that a number of asphyxiated infants who were thought to have atelectasis are in a considerable degree of shock, with an impairment of their pulmonary circulation, and can use oxygen only under difficulty. Eastman [5] states that the oxygen content of the umbilical vein blood at birth may occasionally fall to 5 vol. % without the infant showing clinical evidence of asphyxia. In his series of severely asphyxiated infants [5] the oxygen of the umbilical vein blood varied from 0 to 2.9 vol. %. The active transport of oxygen by the air lock under a physiological pressure and with the removal of carbon dioxide offers a safe means of resuscitation involving no exhausting physical effort on the part of the resuscitating physician to supply oxygen and no crippling activity on the infant's part to use that oxygen. Eastman [5] warns against using physical stimulation when the infant is cyanotic and, as stated previously, insists that the essential treatment of asphyxia neonatorum is the introduction of oxygen into the circulating blood of the infant.

It is believed that the asphyxiated newborn infant can absorb considerably more than 10% of his oxygen requirements through his skin. It is known that this amount [10] can be absorbed by diffusion through the skin of the adult unclothed and surrounded by an atmosphere of 100% oxygen. The initial relief of cyanosis seen in many infants when they are placed in the lock under increased pressure suggests that a considerable amount of oxygen is absorbed through the skin and upper respiratory passages.

It has been thought that many of these asphyxiated infants could not breathe because of the presence of a tracheal or bronchial plug of mucus or fluid, and that the use of a tracheal catheter or the bronchoscopic examination, with the subsequent removal of the plug and the carrying of oxygen down the trachea, would be of value.[11] Potter [12] states, however, that

> The presence of excessive amounts of amniotic fluid within the lungs at the time of birth is of little consequence and does not interfere with the entrance of air. The rich capillary bed of the alveolar walls absorbs fluid rapidly, and air probably enters as easily as if excessive amounts of fluid had not been inspired.

This has been my experience in the resuscitation of asphyxiated infants with the air lock.

House and Owens,[13] on bronchoscopy of 23 infants, were able to find in only one case a plug of exudate in a single bronchus. A progressive improvement in the infant's respiration, with complete relief taking place most frequently from 6 to 8 hr. after instrumentation, occurred in the authors' series of asphyxiated infants.[13] Prompt relief does not occur at once, which clearly shows that it is theoretically and practically impossible to remove enough pulmonary fluids for immediate relief of the asphyxiated newborn infant by means of a tracheal tube, whether a bronchoscope or a tracheal catheter.

Removal of pulmonary fluids must be accomplished by the infant or through expansion of gases to express fluids and secretions.

This means of expelling pulmonary fluids by the expansion of gases is the best theoretical and practical method available at present. Table 5 shows the results of the use of expansion of gases to expel fluids and secretions in this series of 100 asphyxiated infants. A total of 23 infants in the series expelled pulmonary fluids. The quantity of these fluids varied from a few cubic centimeters to very large amounts. For the most part, the fluids were clear and frothy, but in a few instances they appeared to be mucopurulent. Two infants expelled blood-tinged mucus, one of whom had been initially resuscitated with the use of a tracheal catheter and as a last resort placed in the air lock. After an initial period of benefit, the respirations became greatly embarrassed and he was removed from the air lock. It was found that this infant had a pneumothorax, and at autopsy three puncture wounds were observed in the lower lobe of the right lung.

Brief postmortem studies on 10 of the 24 infants processed in the air lock are given below.

Baby J., a boy of 30 weeks' gestation, weighed 3 lb. 12 oz. (1,701 gm.) after breech delivery with double footling presentation. He lived 24 hr. Autopsy diagnoses were slight subdural hemorrhage, slight subarachnoid hemorrhage, hyaline membrane in lung, and bilateral atelectasis.

Baby R., a boy of 34 weeks' gestation, weighed 4 lb. 9 oz. (2,070 gm.) after breech delivery. He lived 23 hr. 45 min. Autopsy diagnoses were subdural and intraventricular hemorrhage, bilateral tear of tentorium cerebelli, edema of the brain, partial atelectasis of lung, and petechial hemorrhages into the heart.

Baby E., a boy of 30 weeks' gestation, weighed 4 lb. 15 oz. (2,240 gm.) after low forceps delivery. He lived three days after removal from the air lock and died of erythroblastosis fetalis, kernicterus, and partial atelectasis.

Baby S., a boy of 38½ weeks' gestation, weighing 6 lb. 10 oz. (3,005 gm.), was delivered spontaneously. He lived 12 hr. Anatomic diagnoses were erythroblastosis fetalis and atelectasis of lungs.

Baby K., a boy of 34 weeks' gestation, weighed 3 lb. 15 oz. (1,786 gm.) after breech delivery. He lived 4 hr. 15 min. Diagnoses at autopsy were tear of tentorium cerebelli, subdural hemorrhage, and atelectasis of lungs.

Baby C., a boy of 40 weeks' gestation, weighed 8 lb. 12 oz. (3,969 gm.) after breech delivery. He lived 22 hr. Autopsy diagnoses were hemorrhage into the right side of the chest, fracture of left clavicle, tear of tentorium cerebelli, subdural hemorrhage, and bullous emphysema.

Baby M., a boy of 38 weeks' gestation, weighing 5 lb. 6 oz. (2,438 gm.), lived 5 hr. 30 min. after midforceps delivery. Diagnoses on autopsy were tear of tentorium cerebelli, subdural hemorrhage, right pneumothorax, right parenchymal hemorrhage, and multiple focal areas of atelectasis on both sides. The right lung showed three minute rents near the anterior lateral margin of the lower lobe.

Baby B., a girl of 36 weeks' gestation, weighing 4 lb. 10 oz. (2,098 gm.), was delivered by cesarean section because of placenta previa. She lived 6 hr. The autopsy diagnoses were bilateral atelectasis and multiple subpericardial hemorrhages.

Baby M., a boy of 28 weeks' gestation, weighed 2 lb. 4 oz. (1,021 gm.). There was prolapse of the cord, with a double footling breech delivery. The diagnosis on autopsy was internal hydrocephalus.

Baby D., a boy of 23 weeks' gestation, weighing 1 lb. 15 oz. (878.8 gm.), was delivered spontaneously. He lived 2 hr. 14 min. The autopsy diagnosis was atelectasis.

In the above group of 10 infants studied at autopsy, five had tentorial tears, in four instances associated with a breech delivery. Two infants had severe erythroblastosis fetalis, and one a congenital malformation of the brain. No bronchial secretions or tracheal plugs were seen in any of these autopsied infants.

Table 6 shows the results from use of the tracheal catheter.

In the group of 24 infants in this series subjected to tracheal catheterization, expansion of gases in the air lock removed fluids in only four. In the group of 23 infants from whom fluids were removed by the expansion of gases, the tracheal catheter was used but four times. This suggests that it is impossible for the resuscitating physician to determine to any degree of accuracy which infant the tracheal catheter theoretically might benefit. Even with using it in the correct infant, the physician may not be able to remove much of the pulmonary fluids and secretions. The risk of trauma is so great that tracheal catheterization is associated with a considerably increased mortality, and an occasional puncture of lung or stomach occurs. It is hoped that the use of this instrument, even in intelligent hands, be discontinued in view of the above findings.

TABLE 6.—*Use and Nonuse of Tracheal Catheter for Oxygenation and Removal of Pulmonary Fluids in Premature Infants*

	Tracheal Catheter Used in Resuscitation		Nonuse of Tracheal Catheter

The increased hydration with edema, seen so frequently in the newborn premature infant, makes its appearance quite early in many of the premature infants placed in the air lock. It is thought that the premature infant easily shifts his vascular fluids to the extracellular spaces because of his low blood-serum proteins, particularly albumin. This accounts for the excess hydration at birth and later loss of weight during the first few days of life. The atelectatic and immature lung of the premature infant probably absorbs more pulmonary fluid in proportion than the mature lung of the full term infant.

The amount of tissue hydration occasionally seen in the premature infant placed in the air lock does not seem to be more than that produced by labor contractions in the premature infant spontaneously starting his respirations and not requiring the air lock. This increased hydration may be of considerable physiological value to the premature infant in the first few days of life, in that administration of fluids does not have to be started immediately. This gives the premature infant a chance to become accustomed to extrauterine life without a great deal of handling and manipulation.

A few infants have been observed to show an unusually prompt physiological jaundice. This is believed to be caused by an early and adequate oxygenation, leading to a quick destruction of the excess blood in the newborn infant.

SUMMARY

A preliminary report is made on a series of 100 asphyxiated newborn infants, occurring in a group of 1,786 deliveries, resuscitated by a positive-pressure oxygen air lock.

The initial absorption of oxygen through the skin and upper respiratory tract is most important. Increasing the pressure of oxygen available for this method of absorption is a vital step in resuscitation.

The expansion of gases expels fluids and secretions from the upper respiratory tract and lungs in approximately one of four asphyxiated newborn infants. The expansion of gases to expel fluids and secretions from the upper respiratory tract and lungs makes unnecessary the use of tracheal suction with its attendant trauma. The use of the tracheal catheter should be discontinued because of an abnormally high associated mortality.

Positive-pressure resuscitation subjects the asphyxiated infant to no physical stimulation on the part of the physician or nurse.

The positive pressure employed by the mother in labor and used in this study subjects the asphyxiated infant to no danger and has been continued for periods as long as 10 days for the premature infant.

The mortality rate in a large maternity hospital has been lowered with the associated lowering of the incidence of premature deliveries and the use of the positive pressure oxygen air lock in the resuscitation of the asphyxiated newborn infant.

ABSTRACT OF DISCUSSION

Dr. Arthur H. Parmalee, Beverly Hills, Calif.: I believe the premises on which Dr. Bloxsom's method is based need to be reviewed in order to evaluate it properly. Discussion of the mechanisms involved in the initiation of respiration in such texts as Windle's "Physiology of the Fetus," Smith's "Physiology of the Newborn," or Barcroft's "Researches on Prenatal Life," reveals the uncertain state of knowledge about what actually goes on in the initiation of postnatal pulmonary respiration. Smith aptly stated the case in these words: "Until we know why most babies breathe when they emerge from the uterus we shall scarcely be sure why some babies do not." Oxygen is the fundamental need of the asphyxiated newborn. Dr. Bloxsom's method accomplishes at least two things that are advantageous to the infant: First, it favors absorption of oxygen through the skin and the mucous membrane of the upper respiratory tract, sufficient perhaps to tide the baby over until such time as respirations may spontaneously begin. Second, it certainly locks the infant up, safe from meddlesome and unintelligent treatment. I am a little frightened by mechanical devices. They are so impersonal, and there such great temptation to place too much reliance on them. Their use tends to exclude personal responsibility for and individual evaluation of the patient in question. It would seem, in my opinion, more important that physicians and nurses be trained to understand something of the physiological processes in fetal and neonatal life, so that they can have an intelligent approach to the problems involved in asphyxia neonatorum and the kind of treatment indicated in individual cases.

Dr. Robert A. Johnston, Houston, Tex.: Admitting that the first few hours and the first day of life are the most perilous for the newborn, one understands the great interest the obstetrician has in any immediate resuscitative measure, as well as any continued supportive aid for the infant during this hazardous period. It is my opinion that the lock resuscitator, in exerting its positive pressure, fulfils such requirements for the newborn infant. The older methods of resuscitation employed by members of the profession not only have been of questionable success but most likely should be considered harmful. The insertion of a gauzed finger into the mouth and throat to wipe out mucus, thus injuring the mucous membranes; the grasping of the tongue with an Allis clamp and the periodic tugging on same; the uncontrollable pressure of mouth-to-mouth breathing; the frequent immersion of a shocked infant from a warm to a cold tub of water; the stretching of the sphincter ani muscle by inserting an oversized finger into the rectum; the intermittent jackknifing of the infant as well as the forceful compression of the chest of the distressed infant by the hand of a well-meaning attendant; even the spectacular tossing of the infant into the air, as advocated by Schultze—all these measures, judged by present-day knowledge, seem not only questionable but definitely unjustifiable. Any infant withstanding such treatment deserves to survive, although it may have "cauliflower" ears and healed multiple fractures to exhibit to posterity. Looking back over a private obstetrical practice of about thirty years, I am forced to question whether one is justified in doing more than draining the respiratory passages of the infant by gravity, preventing the loss of heat whenever possible, and occasionaly exerting nontraumatizing external sensory stimulation. The careful employment of the infant bronchoscope, especially in cases in which there is the "tapioca" type of amniotic fluid or evidence of an obstructed bronchus, needs no comment. The administration of drugs as a respiratory stimulant is of merit in some cases. With the use of the lock resuscitator, one can dispense, in practically all cases, with the tracheal catheter and its attending danger. To reduce infant mortality, a triple responsibility is shared by the anesthetist, the obstetrician, and the pediatrician. The cooperation of such a team, along with a well-regulated premature nursery, inevitably leads to a reduction in infant mortality. The lock resuscitator invented by Dr. Bloxsom is a boon to the obstetrician, the anesthetist, and the pediatrician. I have witnessed its efficacy repeatedly. The infant can be constantly observed, and at the same time it is protected from being handled or injured by well-meaning but overzealous accoucheurs. The temperature and the amount of oxygen, as well as the humidity, are automatically controlled for the optimum benefit to the infant. Correctly timed intermittent forced pressure takes the place of sensory stimulation. It is astounding to see the amount of fluid that the infant may express from the respiratory tract. I have witnessed its marvelous achievement of resuscitating several infants and its keeping these babies alive thereafter. The change for the worse in some of the premature infants removed only for a short interval from the resuscitator was so marked that no doubt was left concerning its lifesaving value. The resuscitator will perform the impossible. The newborn still needs the alertness, care, and keen judgment of the triumvirate mentioned. I believe statistics in the future will confirm that the lock resuscitator offers the most ideal place for the newborn infant, especially if distressed, to spend the most perilous period of its life.

Dr. Allan P. Bloxsom, Houston, Tex.: The question has been asked whether the fluid comes from the pulmonary tree or from the stomach. The reasons that suggest its coming from the pulmonary tree are (1) that the fluid is frothy, as a rule, and in the form of small bubbles and (2) that the fluid is expelled, for the most part, when the pressure in the lock is being decreased. If the fluid were coming from the stomach, one would expect it to be smooth and to appear when the pressure in the lock is being increased.

Toxemias of Pregnancy.—Two main types of hypertensive pregnancy toxemia are seen. The preeclampsia-eclampsia complex has received considerable attention, but the more permanent arteriosclerotic toxemia very little. Vital statistics indicate that the latter is more important as a cause of maternal death than the former, since there is, even in the absence of further pregnancies, a 20 per cent ten-year mortality and in their presence a 40 per cent rate. It has been estimated that about 40 per cent of the toxemias of pregnancy are of this type.—F. E. Whitacre, M.D., Obstetrics and Gynecology, in Medicine of the Year: Philadelphia, J. B. Lippincott Company, 1951, p. 83.

CLINICAL NOTES

ALKALOSIS DUE TO HYPERVENTILATION

A REPORT OF THREE CASES

Theodore H. Sattler, M.D.
Gilbert H. Marquardt, M.D.
and
George M. Cummins Jr., Chicago

Recently one of us (G. H. M.) reviewed the factors involved in the regulation of acid-base balance and pointed out the necessity of actual determination of the blood pH for correct differentiation of respiratory and metabolic acidosis and alkalosis.[1]

Breathing in excess of the physiological requirements removes excessive quantities of carbon dioxide from the blood and tends to produce alkalosis. Hyperventilation may be severe enough to overcome the compensatory mechanisms, and the pH of the blood then rises above the accepted upper limit of normal (7.45). Symptoms that result include tingling of the fingers and toes, numbness of the face followed by carpopedal spasm and ultimately by generalized spasms, convulsions, delirium and disorientation.

Alkalosis due to hyperventilation may be induced in a number of ways as outlined by Peters,[2] and Cantarow and Trumper[3]: acute hyperventilation, which occurs in unstable persons under sudden emotional stress; fever hyperventilation, which occurs because of increase in body temperature; high external temperature, which, if prolonged, may result in primary carbonic acid deficit; anoxic anoxemia, which occurs as a result of high altitudes and lowered atmospheric oxygen tension, producing the primary carbonic acid deficit; lesions of the basal ganglia, such as encephalitis, which produce hyperventilation over long periods of time.

A review of the literature reveals no clinical reports of hyperventilation alkalosis. Three cases of respiratory alkalosis are presented to illustrate several unusual features and to further emphasize the importance of venous blood pH determinations in the diagnosis and treatment of this disorder.

REPORT OF CASES

CASE 1.—Mrs. E. D., a 31 year old white woman, was admitted to the hospital in December, 1948, with the complaint, of two months' duration, of frequent attacks of shortness of breath associated with dryness of the mouth, a tight feeling, and a sensation of a "lump" in her throat. A constricting feeling in her chest usually followed. Occasional accompaniments were numbness of the upper lip, vertigo, and headache. Inventory of symptoms was noncontributory as was the past history. Physical examination revealed a somewhat obese (180 lb. [81.6 Kg.]) white woman, with blood pressure of 96/66. The pulse, temperature, and respirations were normal. The remainder of the physical findings were essentially normal.

Laboratory studies included the following data: Red blood count was 4,240,000, hemoglobin 94%, and white blood count 9,000. Differential blood count showed no abnormalities. The urine contained no albumin, sugar, or blood cells. Blood chemical studies (expressed in milligrams per 100 cc. except as indicated) showed nonprotein nitrogen 27, glucose 107, calcium 10.5, phosphorous 3.77, albumin 3.98 Gm., globulin 1.90 Gm., and cholesterol 206. Vital capacity was 3,400 cc. (normal 3,760). The electrocardiogram showed no diagnostic deformities. X-ray study of the chest revealed no cardiac or pulmonary pathology. Barium study of the esophagus was normal. Dehydrocholic acid (decholin®) circulation time was 14 seconds, and the venous pressure was 144 mm. of water.

During her hospital stay the patient experienced two minor episodes of dyspnea and tightness of the chest. These were very mild and disappeared gradually without treatment. A laryngoscopic examination during an attack was normal, and physical examination on both occasions was normal except for an increased rate of respiration. When the patient was asked to voluntarily hyperventilate for 10 minutes, a typical attack was reproduced except for the absence of chest distress. The hyperventilation test was then repeated after we had obtained an initial venous blood pH determination, which was 7.35.

After 12 minutes of hyperventilation, the venous blood pH rose to 7.55, and again the typical symptoms of the "attacks," including a constricting sensation of the chest and throat, numbness of the lips, dizziness, and headache, were produced and persisted for two hours, after which the patient again felt perfectly well. At present, 24 months after her discharge from the hospital, this patient continues to have only an occasional, mild, symptomatic episode, which is easily dissipated when she consciously slows her rate of respiration.

CASE 2.—G. S., a 56 year old white woman who was under observation for "anginal" pain syndrome at Wesley Memorial Hospital in March, 1948, was seen one evening because of sudden dyspnea. She complained of shortness of breath, a constricting sensation in her throat, and numbness of the face and both hands. The patient had a respiratory rate of 38 and severe carpopedal spasm. Her symptoms were dramatically relieved by reassurance, calcium gluconate given intravenously, and conscious effort on her part to slow her respiratory rate. The physical examination was essentially normal, and the past history was noncontributory.

The following information was obtained from the laboratory. The urine showed a trace of albumin but no sugar. Red blood count was 4,360,000, hemoglobin 83%, and white blood count 5,100, with a differential count within normal limits. Sedimentation rates were 17 and 20 mm. (normal under 20). Blood chemical studies (in milligrams per 100 cc.) showed nonprotein nitrogen 29.9, cholesterol 206, calcium 9.2, and phosphorous 4.3. Electrocardiograms taken at four day intervals were essentially normal and showed no diagnostic changes. X-ray examination of the chest was considered to be within normal limits.

Two days after the above described attack, a hyperventilation test, as outlined earlier, was carried out. Venous blood pH prior to the test was 7.37, and after only five minutes of active hyperventilation, the typical symptoms of which she originally had complained were reproduced, including dizziness, slight headache, numbness of face, and tingling and numbness of the hands; no carpopedal spasm developed, however. Blood pH was 7.49. These symptoms were identical in onset and character with the attack experienced previously except for the absence of carpopedal spasm. At the present writing, 21 months later, the patient remains free of any distress and has had no symptoms suggesting a recurrent episode.

CASE 3.—Mr. T. R., a 40 year old white man, was under treatment at Wesley Memorial Hospital in February, 1948, for rheumatic heart disease manifested by mitral stenosis and insufficiency, aortic stenosis, auricular fibrillation, and marked decompensation. The patient was receiving routine treatment for decompensation, including low salt diet, digitoxin, aminophylline, oxygen, meralluride injection (solution mercuhydrin® sodium), and morphine. On the sixth hospital day he became irrational; he began to sing and talked constantly and incoherently. He became incontinent, uncooperative, and difficult to restrain. The diagnosis of a drug psychosis was considered, but because of the pronounced increase in the respiratory rate, a hyperventilation

[3] Cantarow, A., and Trumper, M.: Clinical Biochemistry, ed. 3, Philadelphia, W. B. Saunders Company, 1945, p. 283.

syndrome was thought more probable. No changes in medications were made. The venous blood pH was 7.62. Ammonium chloride therapy was instituted; 1 Gm. was given orally every four hours. The patient, though showing no change in his cardiac status, began showing some improvement 16 hours later, and 24 hours after ammonium chloride therapy was begun, he was completely rational, coherent, and cooperative. Venous blood pH at this time was 7.45. The patient's cardiac status continued to improve slowly, and no recurrence of alkalosis developed.

Three months after discharge from the hospital, he remained compensated on a limited activity basis, and no further bouts of alkalosis had been experienced.

COMMENT

We feel that respiratory alkalosis is an easily produced and probably often overlooked syndrome. As pointed out by Peters [2] and others, in patients who have a slight, asymptomatic, preexisting alkalosis from other causes such as vomiting or excessive alkaline therapy, only moderate hyperventilation is required to precipitate severe symptoms.

The cases presented represent typical hyperventilation syndrome. The alkalosis in cases 1 and 2 was the result of unconscious hyperpnea in usually stable persons and presented a diagnostic problem in differentiation from cardiac disease. Case 3 illustrates the extremes to which this process may go and the importance of prompt and accurate diagnosis and treatment in an acutely ill patient.

Venous blood pH determinations were made on a standard Coleman pH meter, as previously described by one of us (G. H. M.).[1] A sealed glass electrode chamber is fitted with a sterile 2 inch length of rubber tubing, to the end of which is attached a sterile 1 inch needle. To the aspirating side arm of the chamber are attached another 1 inch length of rubber tubing, a thumb clamp, and a 2 cc. syringe. The pH meter is standardized prior to each determination with a standard buffer solution of pH 7.4. About 2 cc. of sterile water is drawn into the chamber. The patient's arm is cleansed with alcohol, a tourniquet placed above the elbow, and 1 cc. of blood is drawn from a vein into the vertically held chamber. The tubing and needle are removed from the chamber, and the latter is placed immediately in the meter. The pH is read directly. Readings are obtained 10 to 20 seconds after the needle punctures the vein and usually 20 to 40 seconds after the application of the tourniquet.

The practicability of venous blood pH determinations has been previously discussed.[1] Furthermore, the ease and rapidity of the test makes it a most valuable clinical aid in the correct interpretation of acid-base disturbances.

SUMMARY

The practical clinical application of venous blood pH determinations is illustrated by three cases of alkalosis due to primary carbonic acid deficit caused by hyperventilation. The value of venous blood pH determinations in acid-base disturbance is discussed, and the etiology of hyperventilation alkalosis is reviewed.

Pathology.—Pathologists in charge of hospital laboratories should be trained and interested in clinical pathology. The primary fixation on, and interest in, pathologic anatomy by many who call themselves pathologists is probably the greatest sin in pathology today. . . . Clinical pathology in the small and medium-sized hospital is in the hands of technicians, and this is not good medicine.—Trends in Pathology, *American Journal of Clinical Pathology*, May, 1951, pp. 464-467.

CARDIAC ACCIDENTS FOLLOWING VASOPRESSIN INJECTION (PITRESSIN®)

Irvin L. Slotnik, M.D., Milwaukee
and
Joel D. Teigland, M.D., Wood, Wis.

Vasopressin injection (pitressin®) has become widely accepted as a useful aid in roentgen visualization of the gallbladder. Through its ability to increase peristalsis, vasopressin injection results in rapid expulsion of gas from the intestine, thus removing obscuring gas shadows. The drug may cause only transient and minor toxic reactions. Collins and Root [1] recognized three contraindications: coronary heart disease, hypertension and hypotension (systolic blood pressure under 100). Kirklin [2] in reporting on the use of vasopressin injection in 100 cases, noted no serious ill effects although numerous minor reactions were observed, the most frequent being pallor. Recently, Mills and co-workers [3] directed attention to the possibility of serious myocardial effects of the drug. We observed two cardiac accidents following vasopressin injection during cholecystography. On the basis of generally accepted principles governing its use, no contraindication to the use of the drug was evident in these cases.

REPORT OF CASES

CASE 1.—A man, 63, was hospitalized for upper abdominal pain of two weeks' duration, occurring after fatty foods were eaten and accompanied by vomiting. There was no history of heart disease and no symptoms referable to the cardiovascular system, except for shortness of breath on unusual exertion. The blood pressure was 130/80 in both arms, there was no cardiac enlargement, and no thrills or murmurs were detected. Abdominal examination revealed no evidence of disease. The white blood cell count, sedimentation rate and blood reaction to the Kahn test were normal. A chest roentgenogram and teleoroentgenographic heart studies did not reveal heart disease. An electrocardiogram on the day after admission, including the three standard leads, unipolar precordial leads and unipolar limb leads, was normal.

Because of the history of abdominal pain and fatty food intolerance, gallbladder studies were requested. On April 18, 1949 at 8:00 a. m., the patient was given hypodermically 1 cc. of vasopressin injection with a pressor activity equivalent to 20 U. S. P. posterior pituitary units. (The roentgenograms were subsequently reported as revealing a nonfunctioning gallbladder containing stones.) Five hours after the vasopressin injection, he suddenly complained of severe left precordial pain, radiating into the left shoulder. At this time the patient was in acute distress, dyspneic and bathed in cold perspiration. The blood pressure was 120/90 and ten minutes later fell to 100/80. The pulse was rapid but regular, and the heart sounds were somewhat decreased in volume as compared to previous observations.

There were no abnormal abdominal findings. Clinically, the patient appeared to have had an acute coronary thrombosis.

An electrocardiogram taken that day revealed changes compatible with myocardial infarction. Serial electrocardiographic tracings subsequently showed progressive changes typical of anteroseptal myocardial infarction. The sedimentation rate (Westergren) rose to a peak of 80 and then gradually fell to normal over a period of four weeks, paralleling his clinical course. On the therapeutic regimen for coronary thrombosis, the patient made an uneventful recovery.

Case 2.—A man aged 54 was admitted with a history of recurrent epigastric distress of 12 years' duration, relieved by ingestion of food and antacids. He complained, in addition, of occasional nausea and vomiting. Physical examination and a chest roentgenogram revealed no evidence of pulmonary disease. The heart was not enlarged to percussion, the rhythm was regular, and the rate was 88. Thrills or murmurs were not detected, and the blood pressure was 140/88. Tenderness was noted in the left epigastrium, but no other abdominal abnormalities were present.

On a Sippy regimen, antacids and antispasmodics, the symptoms subsided within 48 hours. A gallbladder series was reported as unsatisfactory due to overlying gas in the bowel. For this reason 1 cc. of vasopressin injection was given hypodermically to rid the bowel of gas and the cholecystogram was repeated. Four hours after receiving the drug the patient complained of moderate shortness of breath followed by nausea and vomiting. The dyspnea suddenly increased, and he became exceedingly apprehensive, clutching at his chest as though in severe pain. He was cold, pale and clammy. His blood pressure was 60/40, the pulse was rapid and regular, and the heart sounds were faint and distant. There were no abnormal abdominal observations. In spite of emergency treatment the patient died within 30 minutes.

At autopsy the heart revealed an old posterior wall myocardial infarction and some concentric hypertrophy of the left ventricle. Healed rheumatic mitral disease without stenosis was present. The coronary vessels showed atheromatous changes with narrowing but no obstruction of the lumens. Some pulmonary congestion with hemosiderosis of the lung was observed. The gallbladder was free of disease.

Death in this case can be attributed to acute coronary insufficiency induced by vasopressin injection. Myocardial ischemia, when prolonged, will lead to myocardial infarction. No actual vascular occlusion is required for infarction to occur; in fact, myocardial infarction without occlusion is by no means unusual. Such prolonged ischemia is a characteristic effect of vasopressin injection, and its results are most damaging when underlying coronary disease is present, as was the case in our second patient.

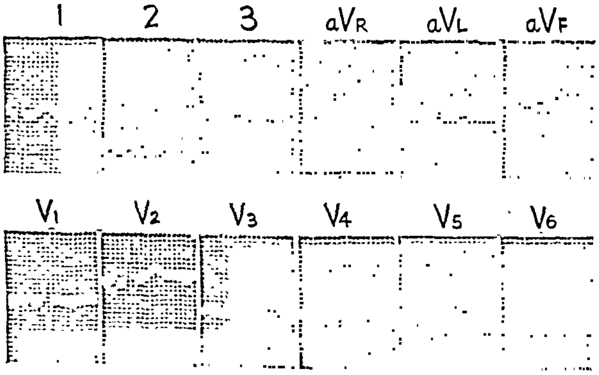

Fig. 1 (case 1).—Electrocardiogram with unipolar limb leads and precordial V leads taken one week before the administration of vasopressin injection.

The absence of myocardial infarction at postmortem examination is as expected, since patients who die after coronary occlusion do not show the usual pathological changes unless they survive six to 12 hours. This length of time is required for the development of necrosis.[4]

COMMENT

That vasopressin injection could be responsible for cardiac accidents is not surprising in view of the experimental work which has been done. Posterior pituitary extract has been shown to have a definite effect not only on the blood vessels and blood pressure but on the heart itself. As early as 1895 the ability of this drug to produce capillary and arteriolar constriction was demonstrated. It was first believed that this vascular constriction was associated with a rise in blood pressure similar to that seen with epinephrine.[5] Later, however, it was shown in the unanesthetized animal and in human subjects that a rise in blood pressure does not occur in spite of capillary constriction. A drop in blood pressure is, in fact, much more characteristic.[6]

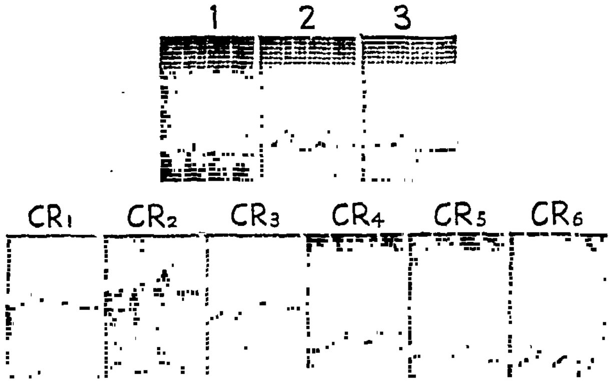

Fig. 2 (case 1).—Electrocardiogram with precordial CR leads taken seven hours after the administration of vasopressin injection.

It has also been demonstrated that pituitary extract results in a slowing of the pulse, associated with sinoauricular block and auriculoventricular block. This response cannot be prevented by administration of atropine or section of the vagi, thus illustrating a direct cardiac effect.[7]

Kamm and associates [8] succeeded in separating pituitary extract into its oxytocic factor and its vasopressor and antidiuretic principle. The vasopressor principle is now known as vasopressin injection (pitressin®), while the oxytocic factor is called oxytocin injection (pitocin®). Experimental work in man utilizing vasopressin injection has revealed essentially the same effects as shown with the crude extract in animals. That a rise in blood pressure does not occur in man was demonstrated by Grollman and Geiling,[6b] who also noted a decrease in heart rate and cardiac output. Collins and Root [1] noted an occasional slight but transient rise in blood pressure. In none of their cases, however, was the blood pressure as high at the end of one hour as it had been before vasopressin injection was given.

Probably the most significant effect of vasopressin injection is its effect on the coronary circulation.[9] Numerous investigations have confirmed that the coronary blood flow is decreased with persistence of this effect for as long as 45 minutes. Green was able to demonstrate intense coronary constriction with depression of the myocardial contractility.[10] In 1944 Dearing, Barnes and Essex [11] showed that acute myocardial degeneration could be produced in cats by administration of large doses of vasopressin injection. That this effect could be produced only in the old animals is particularly interesting in view of the fact that the cardiac accidents which we observed both occurred in older patients. Ruskin [12] actually utilized this deleterious effect of vasopressin injection on the coronary circulation as a test of coronary insufficiency. He demonstrated resulting bradycardia, premature beats, and S-T and T wave changes.

A significant and peculiar characteristic of vasopressin injection is the long duration of myocardial ischemia which it can produce and its unusually long latent period. This is well illustrated by our two cases, in which four and five hours passed before the cardiac effects became evident. Similar observations were made by Mills in his four cases in which latent periods of 4 hours, 2 hours, 1½ hours and 20 minutes were noted prior to onset of cardiac symptoms. The prolonged ischemia is probably an important factor in the serious reactions which have been recorded, since it is well known that prolonged hypoxia, even of mild degree, can result in myocardial infarction.

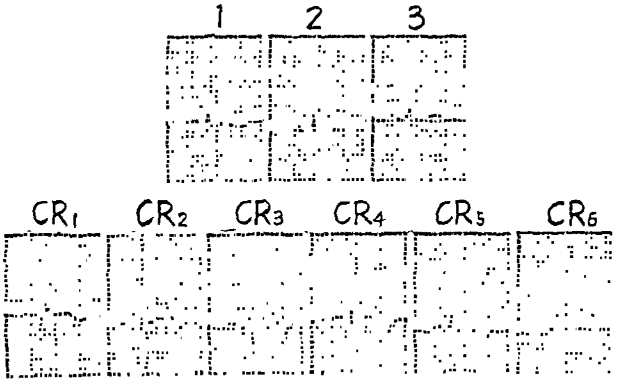

Fig. 3 (case 1).—Electrocardiogram with precordial CR leads taken three weeks after the administration of vasopressin injection.

Vasopressin injection is capable of serious and even fatal cardiac accidents in elderly patients. This is conclusively demonstrated by our cases and those of Mills. Whether it can produce such effects in the normal young heart is, however, by no means determined. Neither in our cases nor in those of Mills has underlying coronary heart disease been eliminated as a factor. In our one case with autopsy and in the two of Mill's cases with postmortem examination, old myocardial infarcts were found. In addition, all these cases are in the age group between 54 and 65, which suggests that coronary arteriosclerosis may have been a factor. A normal electrocardiogram such as we noted in our first case prior to the administration of vasopressin injection, and which was also noted in two of Mill's cases, does not rule out the possibility of underlying coronary heart disease. The frequent observance of normal electrocardiographic tracings even in persons with advanced coronary insufficiency is well recognized.

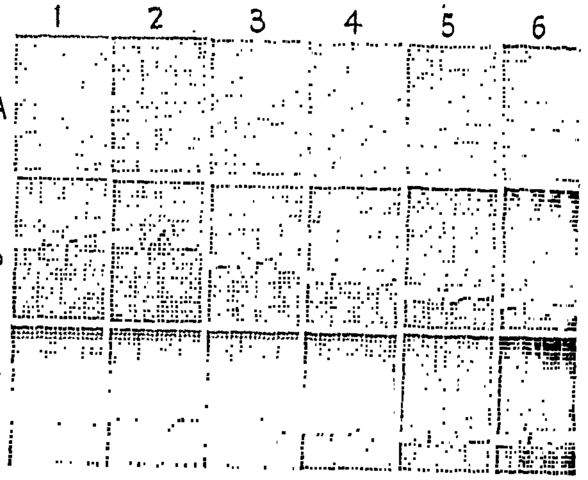

Fig. 4 (case 1).—*A*, precordial V leads taken one week prior to the administration of vasopressin injection; *B*, precordial CR leads taken three weeks after the administration of the drug, and *C*, precordial CR leads taken seven hours after its administration.

Certainly there is general agreement that vasopressin injection should be withheld in the presence of coronary insufficiency. It appears that a routine electrocardiogram before the utilization of vasopressin injection would be a wise procedure. Though an abnormal tracing contraindicates use of the drug, a normal electrocardiogram does not assure one that it can be given with impunity.

Perhaps it would be best to withhold vasopressin injection entirely in older persons. Great care must be taken to differentiate the symptoms of gallbladder disease from those of coronary insufficiency when the use of vasopressin injection is contemplated. That the symptoms of gallbladder disease can be mimicked by coronary insufficiency induced by a large meal is well known. Despite the fact that gall stones were found in our first patient, it is quite possible that his symptoms were actually those of coronary insufficiency.

SUMMARY

Vasopressin injection (pitressin®) has proved to be useful for the elimination of confusing gas shadows during cholecystography. It has been generally accepted as a safe medicament. Extensive experimental work in the past has demonstrated profound cardiovascular effects resulting from its use, the most important being a decrease in coronary blood flow. An instance of proved myocardial infarction and a death following the administration of vasopressin injection are reported. It is suggested that the drug be used with caution, if at all, in elderly patients.

COMPLETE OBSTRUCTION OF THE ESOPHAGUS FOLLOWING SERUTAN® INGESTION

C. L. Hinkel, M.D., Dunville, Pa.

In the course of hospital practice of radiology it is not uncommon to find obstruction of the esophagus in patients who have symptoms of brief duration. The commonest non-neoplastic obstruction is that resulting from impaction of meat or some other foreign body. The finding of obstruction of the lower end of the esophagus following the ingestion of the proprietary preparation known as serutan® is unique in our experience. In 1937 and also in 1939 saraka® (a hygroscopic gum laxative) was reported as causing esophageal obstruction.[1] Since that time we have seen no reports of such cases in the literature.

Serutan,® a bland granular hygroscopic substance, which is widely used as a remedy for constipation, is said by the manufacturers to be a hydrogel derived from Plantago ovata and extracted sugar beets from which the roughage has been removed. Apparently, serutan® owes its laxative properties to its gelatinous, spongy character and its ability to absorb and retain liquids, with a corresponding increase in bulk.

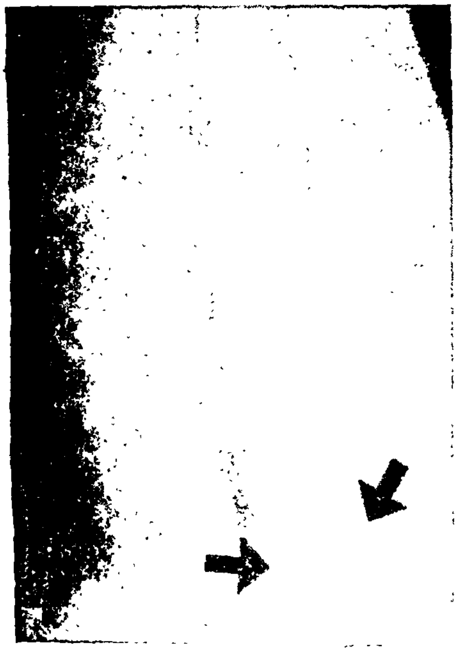

Fig. 1.—Roentgenogram of barium in the esophagus, right anterior oblique projection. The obstruction is complete. Note inverted meniscus sign at the site of impaction, dilatation of the proximal esophagus and a slight spillage of the barium into the trachea.

Because of the rarity of this type of esophageal obstruction, the following case is reported in brief.

REPORT OF CASE

H. B., a 75 year old white man, was referred to this hospital by his family physician on March 3, 1950, complaining of pain in the chest, a feeling of "bursting" behind the sternum and inability to swallow.

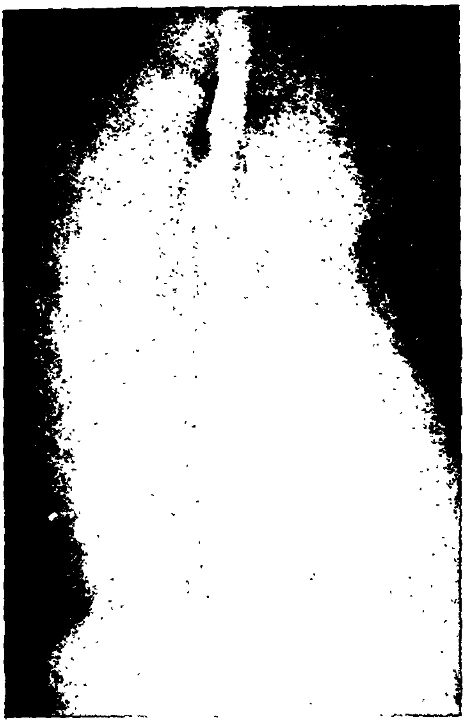

Fig. 2.—Postoperative roentgenogram of barium in the esophagus, right anterior oblique projection. The obstruction has been removed. The esophagus appears normal.

The patient stated that he was troubled with constipation and that on March 11 he took two doses of serutan® without untoward symptoms. He took two doses in the same manner on the following two days, March 12 and 13. On March 14 he swallowed the serutan® in the following manner: Two teaspoonfuls of dry serutan® was placed in a cup and 1 teaspoonful was swallowed and washed down with a few sips of water. The second teaspoonful was then taken and washed down with the remainder of a glass of water.

Within five minutes after ingestion of the laxative the patient had a feeling of oppression and felt that his "gullet" was filling up. He expectorated a great deal of mucoid and salivary material which he estimated to be about 1 pint (473 ml.). Pain developed in the epigastric and retrosternal regions and continued and increased in severity until the time of his admission. After the development of these symptoms he was unable to swallow anything. The patient went to bed but had so much pain and salivation that he was unable to sleep. His physician gave him tablets, which he chewed and swallowed. This caused him to gag, bringing up a considerable quantity of liquid mucoid material, the fragments of the tablets and a chunk of sticky, tough material that he estimated to be 1½ or 2 inches long (3.8 or 5 cm.), resembling a piece of sausage. The patient stated that this looked like some of the serutan® which he had taken. The symptoms of obstruction persisted all night in spite of a morphine injection, and the next morning he was admitted to the hospital.

From the Department of Radiology, George F. Geisinger Memorial Hospital and Clinic.

[1] Goldman, J. L.: Esophageal Obstruction from Hygroscopic Gum Laxative (Saraka), J. A. M. A. **108**: 1408 (April 24) 1937. Waltz, M. R.: Esophageal Obstruction Resulting from Injudicious Method of Ingesting Hygroscopic Gum Laxative (Saraka): Esophagoscopic Removal, ibid. **112**: 229 (Jan. 21) 1939.

Physical examination was noncontributory except for evidence of arteriosclerosis. The diagnosis of obstruction was made at once, and the patient was given papain suspension, which was regurgitated promptly. Urinalysis of a specimen secured on admission and all laboratory tests revealed no abnormality except for a white blood cell count of 18,200, of which 86 per cent were polymorphonuclear cells.

Roentgenological Examination.—Under fluoroscopic control the patient was given a drink of barium sulfate suspension. There was complete obstruction in the lower third of the esophagus, and no barium entered the stomach. The inferior end of the barium column in the esophagus outlined a smoothly rounded mass, and in the erect position some of the barium tended to surround the mass, producing the typical inverted meniscus sign frequently associated with meat impaction. The esophagus was somewhat dilated proximal to the obstruction, and some of the barium spilled over into the trachea, producing a paroxysm of coughing (fig. 1).

Esophagoscopy.—On March 15, 1950, a 9 mm. by 53 cm. full lumen esophagoscope was introduced without difficulty. The esophagus contained a large amount of saliva and some barium. After this was aspirated the mucosa was found to be edematous and congested. Three inches (7.6 cm.) above the diaphragm the lumen was completely obstructed by pasty, granular, brown material that looked somewhat like brown sugar. It was sticky and cohesive and was removed with great difficult as the aspirator frequently became clogged. Some of the material was removed with forceps. The mucosa in the area of the obstruction was noted to be extremely dry, granular and inflamed.

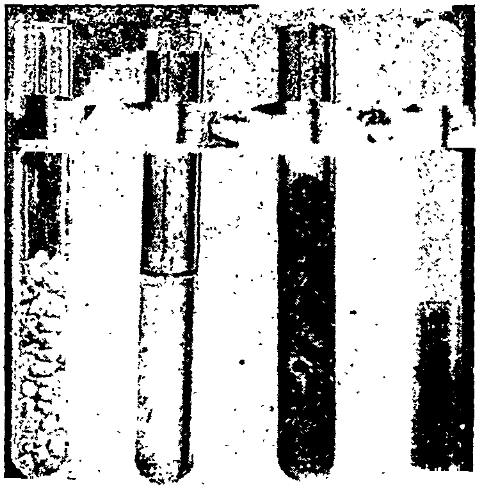

Fig. 3.—Simple test tube demonstration: tube 1, dry serutan®; tube 2, water; tube 3, water and serutan,® mixed; tube 4, water and serutan mixture inverted without spilling.

After the removal of all of the material, a no. 20 bougie was passed into the stomach without further obstruction.

Hospital Course.—The patient was given dihydrostreptomycin, 0.7 Gm. intravenously twice a day, and also fortified crystalline procaine penicillin G (duracillin®) 400,000 units every six hours, in order to combat the local esophagitis.

After the removal of the impaction, the symptoms disappeared. The patient was able to swallow, and reexamination of the esophagus, stomach and duodenum by roentgenoscopic and roentgenographic means disclosed no abnormal findings in the esophagus or stomach. The normal postoperative roentgenogram is reproduced in figure 2.

FURTHER INVESTIGATIONS

Because of the unusual interest of this case, a supply of serutan® was secured from a local drug store, and the hygroscopic nature and interesting physical properties of the substance were investigated. It was found that when water was added to the dry serutan,® the granular material quickly became wet, swollen and spongy. If insufficient water was added, a semisolid gel was formed which on standing became firmer and firmer. When equal quantities of serutan® and water were mixed together in a test tube, the mixture stiffened so quickly that in 30 seconds it was possible to invert the tube without spilling the contents.

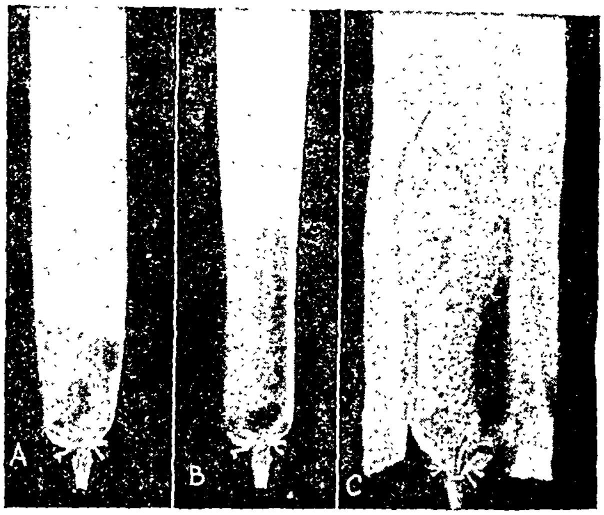

Fig. 4.—*A*, dry serutan® in a 1 inch (2.5 cm.) rubber Penrose drain. *B*, water added to serutan® in the rubber drain. Material is swollen, spongy and granular but firm to palpation 30 seconds later. *C*, rubber drain cut open, exposing the wet, gelatinous, cohesive serutan® that retains the form of the tube.

A simulated esophagus was made by tying off a piece of rubber Penrose surgical drain 1 inch (2.5 cm.) in diameter. When serutan® and water were mixed in this drain, it was found that considerable swelling took place and that within 30 seconds the mixture became quite firm to palpation. Within two minutes an impaction had formed which was so firm that when the rubber tubing was cut open, the sausage-like mass could be held easily in the fingers (fig. 4 and 5).

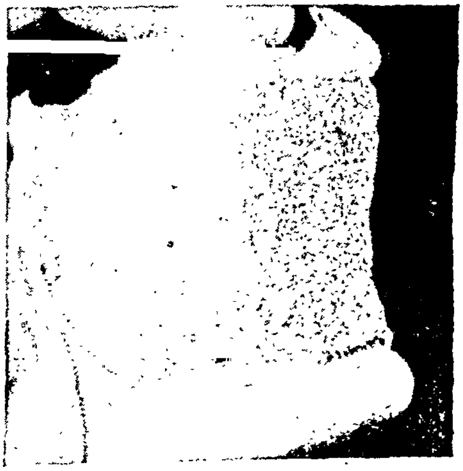

Fig. 5.—Two minutes after addition of water the serutan® can be held in the fingers much like a piece of sausage.

COMMENT

From the results of the simple experiments described above, the patient's history and the absence of demonstrable esophageal disease we formed the opinion that the unusual obstruction of the lower end of the esophagus in this patient was the result of the rapid swelling of the;

serutan® during its passage through the esophagus. It is likely, of course, that there was some delay in the esophagus as the result of temporary cardiospasm or other transient constriction. No organic disease of the esophagus was found that might explain the delay which presumably occurred. Probably the patient swallowed an insufficient amount of water with the dry serutan,® and the limited amount of water favored the production of a semisolid mass which obstructed the lumen; hence when the remainder of the glass of water was ingested, the impaction was already present. The local esophagitis noted at the time of esophagoscopy was presumably the result of local dehydration of the mucosa, together with continued swelling of the serutan® mass, producing stretching of the esophageal walls. It would seem wise to advise patients who use the substance, or other similar hygroscopic substances, to observe the precaution of ingesting copious amounts of water or other liquids that will quickly wash it into the stomach before impaction can occur in the lower esophagus.

SUMMARY

An unusual case of esophageal obstruction is reported. This presumably resulted from the ingestion of dry serutan® followed by an insufficient fluid intake. The typical roentgenological characteristics of such an impaction are presented.

COUNCIL ON PHARMACY AND CHEMISTRY

The Council on Pharmacy and Chemistry has authorized publication of the following report to the Council.

R. T. Stormont, M.D., *Secretary.*

RADIOACTIVE ISOTOPES IN MEDICAL RESEARCH, DIAGNOSIS, AND THERAPY

F. E. Kelsey, Ph.D., Chicago

Since the Isotopes Division of the Oak Ridge National Laboratory began the distribution of isotopes for research and therapy in 1946, over 10,000 shipments have been made, more than 40% of which were for medical research, diagnosis and therapy.[1] A large number of radioactive isotopes have been synthesized both by neutron bombardment in a nuclear-reacting pile and by cyclotron. Extensive biologic or medical applications have been made with phosphorus 32, iodine 131, sodium 24 and carbon 14.[2] Radioactive isotopes are generally available in an elemental state or as simple ionic compounds, although the number of radioactive organic compounds that have been synthesized is increasing rapidly.

A radioactive isotope differs from one which is not radioactive only in the composition of the atomic nucleus, generally because of an extra neutron. In most biologic reactions, this additional neutron does not affect the chemical properties of the atom sufficiently to enable living organisms to differentiate the isotope from its natural counterpart. Minor differences in reactivity may be demonstrated; for example, the heavier atom diffuses more slowly, but it still can be used as a tracer in metabolic studies.

The changes in the nucleus cause instability of the atom, and disintegration may occur suddenly. This lack of stability, characteristic of all radioactive isotopes, varies extremely from one isotope to another. The time required for disintegration may be a fraction of a second or several million years. Since stability of the nucleus cannot be increased or decreased by any external factors, the time required for disintegration of half of the atoms in any given amount of material containing isotopes is a direct function of the nuclear stability of each radioactive isotope. This property is referred to as the "half-life" of the isotope (see table). Isotopes with a relatively short half-life are safer for clinical use, since the dose of radiation is limited regardless of the persistence of the element in the body. Radioactive sodium, for example, with a half-life of 14.8 hours, can be given in doses of 40 mc. In 14.8 hours, the amount remaining undecomposed is 20 mc.; in 29.6 hours, 10 mc.; in 44.4 hours, 5 mc.; and, in 3.7 days (6 half-lives) only 0.625 mc. remains.[*] On the other hand, an isotope with a longer half-life can be stored over a longer period of time without appreciable loss of activity.

The biologic effect of an internally administered isotope depends on the nature and intensity of the radiations, the half-life of the isotope, its persistence in the body, and its distribution pattern in the body. For example, the high degree of persistence and the selective localization of radium in the bones result in important biologic effects with doses of radioactivity hundreds of times less than that required with isotopes, such as sodium 24 or phosphorus 32, which are more evenly distributed throughout the body. Furthermore, large doses of any radioactive isotope must be administered slowly, or in high dilution, to prevent local damage at the site of administration. Similarly, some isotopes such as iodine 131 and phosphorus 32, are excreted rapidly and may damage the kidney and bladder.

When a radioactive atom disintegrates, the molecule carrying it is shattered and emanations of the beta, gamma or, less frequently, alpha and neutron types, are emitted from the nucleus. The biologic effects resulting from this disintegration are caused largely by these emanations rather than by the destruction of the molecule.

Alpha particles are heavy, doubly-charged particles composed of two neutrons and two protons and are identical with the nucleus of the helium atom. They produce intense, but localized, damage since they collide with other atoms in the immediate vicinity (within 0.05 mm.) more frequently than do the lower-charged and smaller beta particles.

Beta particles are high-speed electrons having a penetrating power up to 8 mm. (for phosphorus 32) in tissue, but their effects are primarily restricted to the immediate vicinity of the disintegration.

Gamma rays are similar to x-rays and penetrate many centimeters, influencing the intermediate tissues.

Neutrons, because they lack an electrical charge, also penetrate deeply but produce local effects from initial collision anywhere along the track.

The speed acquired by the emanations alters their penetration of tissue. High-energy (fast) neutrons are less subject to collision or capture than low-energy (slow) neutrons. Extremely high-energy beta particles produced by a betatron also have a longer range in tissue. Their high speed permits them to penetrate relatively deep before any appreciable ionization is produced. Since this depth is determined by the original energy of the electron, the betatron can be used to produce intense ionization at predetermined depths, as in the treatment of a deep-seated cancer.[3]

HEALTH HAZARDS AND CONTROL MEASURES

The hazards involved in the use of radioactive isotopes are difficult to evaluate since there are no detectable biologic effects which can be used to discover incipient injury. Since the incidence of leukemia and allied diseases is ten times greater among radiologists than among other physicians, it is evident that the blood-forming organs are sensitive to radiations. Measurement of peripheral blood changes is the best control measure available, but these changes vary among persons and daily in the same person. The methods for measuring the hematologic constituents lack precision also.[4] Routine x-rays of workers who may

---

Because of lack of space, the bibliographic references have been omitted from The Journal. They are, however, included in the author's reprints.

[*] The most commonly used unit of measure for radioactive isotopes is the millicurie (mc.) which is defined as the amount of isotope giving 2.2×10^9 disintegrations per minute. It is roughly equivalent to the number of disintegrations occurring in one milligram of radium.

be exposed to radiation should be taken as seldom as possible because of the additive effect.

The intensity of radiation in an exposure area must be measured to determine the maximum time a person may receive a "permissible" amount of radiation. The permissible limits have been determined on the basis of past experience with roentgen rays and radioactive isotopes occurring naturally (such as radium) as well as from work with animals. This determination is often only an estimate, since the life span of experimental animals is too short to predict the effect on a human being exposed for many years.[5]

The greatest health hazard involved is the accidental ingestion of radioactive isotopes orally or by inhalations of vapors or dusts. Appreciation of the distances over which the various types of emanations are effective is important. Consideration should be given to reflections and secondary radiation.[6] The total body radiation from cosmic rays received by an individual during a 70 year lifetime is 20 to 40 r. Internally deposited, naturally-occurring radioactive isotopes add another 2 to 5 r to this amount. A chest x-ray results in an exposure of 0.4 to 2 r, and a complete gastrointestinal series may amount to as much as 40 to 75 r. Therapeutic application of roentgen rays to limited areas, as in the treatment of skin carcinomas, may be equivalent to 5,000 r or more. The fatal dose of total body irradiation in human beings has been estimated at 400 r. For rats the fatal dose is 825 to 900 r, for guinea pigs 250 r, and for paramecia 300,000 r.

Radioactive Isotopes

			Penetrability of Radiation (Cm.)		
			Beta Radiation		Gamma Radiation
Element	Atomic Weight	Half-Life	Maximum Range in Air	Maximum Range in Tissue	50% Absorption in Tissue*

* *Where no figures appear, there is no gamma emission.*

Government regulations concerning the use of radioactive isotopes produced by the Atomic Energy Commission are relatively strict and formalized.[7] The Oak Ridge National Laboratory, through its Isotopes Division, is responsible for evaluating and approving an organization's facilities and the qualifications of the physicians and research workers desiring to use radioactive isotopes in human experiments. Approved medical organizations (hospitals, clinics, research organizations) must possess adequate facilities for assaying, handling, and disposing of the radioactive materials as well as for the clinical care of the patient. The physician in charge of the radioactive material must have had previous experience in this field, or be directly collaborating with someone who has such experience, and must be in good standing with the local medical society. The Atomic Energy Commission also recommends that the institution appoint an "isotope committee" to approve all proposals for the use of radioactive isotopes in that institution. This committee should consist of a physician trained in internal medicine, a hematologist, an individual experienced in the handling and use of radioactive isotopes who is familiar with the necessary precautions as to shielding and disposal, and a physicist and therapeutic radiologist, at least available as consultants. Further, special permission is required for the use of isotopes having a half-life of more than 30 days, because of their greater potential hazard.

ANALYSIS FOR RADIOACTIVE ISOTOPES

A characteristic property of the emissions from radioactive decay is their ability to produce ionization by collision with other atoms, resulting in the formation of free electrons. These free electrons are easily and rapidly measurable by such instruments as the Geiger counter, the scintillation counter, and the ionization chamber. The Geiger counter, the most versatile and flexible radiation detector, consists of two electrodes, the cathode being a hollow tube and the anode a fine wire suspended along the longitudinal axis of the tube. When an ionizing particle enters the tube, a few free electrons are formed and accelerated toward the center wire. When their speed is great enough, additional electrons are formed by collision with the gaseous atoms, and these are also accelerated toward the center wire. This multiplication process is referred to as an "avalanche" and results in an electric pulse produced when these thousands of electrons arrive at the center wire. The whole process is initiated by the original ionizing event, i. e., the radiation produced by the disintegrating atom. The apparatus thus records this disintegration. Geiger tubes have been designed in a number of shapes and sizes for specific uses. For example, detection of phosphorus 32 in intracranial tumors required the development of a Geiger tube that could be sterilized and used by the surgeon as a probe to pinpoint the source of radiation in the brain.[8]

In addition to the Geiger tube itself, a power supply and scaling circuit is needed. The latter is a rapid electronic recording device which actuates a mechanical recorder after a given number (usually 64) of ionizing events have been received. Integrating circuits are also used to show the counting rate directly, either on a meter or on a continuous recording device.

The use of the scintillation counter to replace the Geiger tube is a recent development. When this apparatus is employed, the radiation is absorbed in a crystal, resulting in a minute flash of light which is detected by a photomultiplier tube and amplifier. It is more efficient than the conventional Geiger counter for measuring gamma-ray emission.[9]

Ionization chambers which do not have internal-multiplying characteristics like the Geiger tube can be used for most work. These fundamentally simple devices use external amplification to measure the rate of fall of an impressed charge between two electrodes, a function of the radiation entering the chamber.

RADIOACTIVE PHOSPHORUS

Phosphorus 32 is a strong beta emitter with a half-life of 14.3 days. It is available as a solution of sodium phosphate with or without a small amount of nonradioactive sodium phosphate added as a carrier. Concentrations as high as 3 mc. per milliliter are obtainable. For each millicurie of radioactive phosphorus administered, the resultant total body irradiation is 10 roentgen-equivalents, which takes into account the half-life and the excretion of part of the dose. It can be given in single doses up to 7 mc. either intravenously or, in smaller doses, by mouth. About 75% of an oral dose is absorbed, the remainder being lost in the feces, and 20 to 40% of each dose is excreted quickly through the kidney. The rest is distributed unevenly throughout the tissues of the body. High concentrations are found in bone and bone marrow and in the liver, spleen, and lymph nodes. The concentration attained in neoplastic tissue may be two to five times that attained in the corresponding normal tissue. This degree of concentration is not sufficient to permit the use of doses adequate for effective irradiation of neoplasms but can be used with Geiger tube probes as a diagnostic aid.[8] The high concentration in bone and bone marrow permits the successful use of this isotope in polycythemia rubra vera. Single doses may result in remissions lasting 6 to 12 months.[10] Isotopic treatment of leukemia is not as successful, although some benefit may be derived,[11] and it is possible that leukemia may result from large doses of phosphorus 32.

The short effective range of the beta radiation of phosphorus 32 and the absence of gamma radiation makes possible the use of this isotope for local irradiation of the skin in conditions such as radio sensitive skin cancers, hyperkeratosis, verrucae, and hemangiomas.[12] Radioactive phosphorus has been used also to measure the effective circulation in an extremity [13] and to label red blood cells to determine red cell volume.[14]

RADIOACTIVE IODINE

Iodine 131 emits both beta and gamma radiation and has a half-life of eight days. The beta emission is responsible for the inhibitory effect on the tissues, while the gamma emission permits a quantitative evaluation of the site of deposition of the isotope within the body. For this purpose a Geiger or scintillation counter is employed externally. Radioactive iodine is available as carrier-free sodium iodide in weak basic sodium sulfate solution containing up to 5 mc. per ml. It is given by mouth in doses of about 1 to 10 mc. and is rapidly absorbed from the gastrointestinal tract and distributed throughout the body. The percentage of retention of radioactive iodine depends on how much iodine pre-exists in the body and to what degree the thyroid gland is active. In normal persons, the thyroid gland will fix 10 to 25% of the dose, and the remainder will be excreted in the urine within 24 hours. In patients with hyperthyroidism, about 50 to 80% of the total dose may be fixed by the thyroid. In myxedematous patients fixation is 10% or less.

Radioactive iodine is used as a diagnostic aid to detect abnormal thyroid function. Various investigators consider this form of iodine particularly valuable for treating toxic goiter.[15] Its use for treating primary carcinoma of the thyroid has not been universally successful since, as a general rule, only low grade tumors, which usually can be cured by surgery alone, take up significant amounts of iodine 131.[16] However, radioactive iodine is of definite value in locating the site of thyroid cancer metastases.[17] Generally, the metastases concentrate iodine in considerably less amounts than does the normal thyroid gland; however, the uptake can be greatly increased by removing the thyroid surgically, by administering thyrotoxic drugs such as propylthiouracil, or by repeatedly administering iodine 131, which destroys the normal thyroid tissue. These procedures are effective probably because they increase secretion of the thyrotrophic hormone of the anterior pituitary and so stimulate the thyroid metastases that their ability to concentrate iodine is increased.[17a] Surgical removal of the normal thyroid is probably the most satisfactory procedure to stimulate the metastatic tissues to concentrate iodine.

The most serious side-effect observed in patients subjected to treatment with large doses of radioactive iodine is a depression of hematopoiesis. In some cases, the urinary bladder may be sufficiently irradiated to cause transient irritation.

RADIOACTIVE SODIUM

Sodium 24 emits both beta and gamma rays and has a half-life of only 14.8 hours. This makes prolonged storage of the isotope impossible, and therefore its use is restricted to centers close to a nuclear pile or a cyclotron. Radioactive sodium spreads rapidly throughout the tissues and fluids of the body, and, because of the gamma emission, can be detected by externally placed counters. The even distribution of sodium has prompted its use in patients with extensive metastases, although it appears to have no particular advantage over x-ray therapy, or as a substitute for total body x-ray in the treatment of such conditions as leukemia and polycythemia rubra vera.

Radioactive sodium has been most useful in the field of diagnosis. When injected intravenously, its course through the heart may be followed by an externally placed, and appropriately shielded, continuous recording counter. Characteristic curves for normal or abnormal cardiac dynamics may be obtained in this manner.[18] Sodium 24 also can be used to measure the extracellular fluid, since sodium is predominantly an extracellular ion. A measured dose of sodium 24 is given intravenously and a sample of plasma is taken later so that the dilution which has occurred with the sodium previously present can be measured. Circulation time can be measured in similar fashion.[19] Further, the time required to attain a constant level of radioactivity in a limb after administration of intravenous sodium 24 indicates whether circulation to that limb has been impaired. Thus, in thromboangiitis obliterans and arteriosclerotic occlusive disease, the uptake in the affected area is much slower. This delineates the area of impaired circulation and helps determine the best amputation site.[20] This isotope has also been used to estimate the efficiency of medical management of impaired peripheral circulation.[21]

RADIOACTIVE CARBON

Carbon 14 is a weak beta emitter with a half-life of 5,600 years. The long half-life of this carbon isotope makes long-term experiments practical; also, important organic compounds containing it may be stocked. On the other hand, the long half-life adds to the hazards of this isotope, since, once fixed in the body, it will continue to irradiate that part until it is excreted. The use of carbon 14 in human subjects therefore must be preceded by exhaustive experiments in animals in order to be certain that neither the isotopic compound itself, nor any isotope-containing metabolites that may be formed, is irreversibly fixed by any part of the body.

The low energy of the beta emission from carbon 14 makes this isotope more difficult to detect than those more commonly used. It is not possible to experiment on intact animals by using external counters. Further, when used for the assay of carbon 14 in isolated tissues, the Geiger counter must be constructed so as to allow the emitted beta rays free access into the counter's sensitive volume. This can be done by using a Geiger tube with a very thin window, usually mica,[2] or by inserting the material to be assayed directly into the counter.[22] Even in the latter case, self-absorption, i. e., the absorption of the beta rays by the material being assayed, can reduce the sensitivity of the analysis by a large factor. This is especially true when the amount of carbon 14 present is very small as compared to the amount of non-radioactive materials present.

Carbon 14 is easily the most useful radioactive isotope for medical research and possesses great potentialities for medical diagnosis and therapy. Since carbon is the basic substance common to all organic materials, a great variety of compounds containing it may be synthesized, useful for two purposes: (*a*) to afford a mechanism for carrying radioactivity to various specific parts and (*b*) to permit the study of metabolism of organic compounds. Although efforts to discover compounds specificially localized to certain tissues or cells have not been very succesful, this approach offers a possible solution to many medical problems.

The preparation of organic compounds containing carbon 14 often presents difficulties. Compounds which can be prepared by ordinary chemical synthesis are being studied in many laboratories. As the supply of chemical intermediates containing carbon 14 continues to increase, problems of synthesis will become easier to solve. However, many substances of great medical interest cannot be synthesized at the present time. Among these natural products are such drugs as the digitalis glycosides, many of the alkaloids (such as those of the opium and the ergot groups), some of the vitamins and sterols, and proteins. For the past four years the Department of Pharmacology at the University of Chicago has been studying the feasibility of growing plants in sealed chambers with the only source of carbon being the carbon dioxide added to the enclosed atmosphere. Varying amounts of carbon 14 can be added as radioactive carbon dioxide. The carbon 14 is thus incorporated at random into all of the constituents of the plant. By growing the appropriate medicinal plant, drugs labeled with carbon 14 can be obtained. To date, digitoxin and other digitalis glycosides,[23] morphine and other opium alkaloids,[24] nicotine,[25] and atropine [26] have been prepared from radioactive plants grown in the laboratory. Currently under investigation are convallatoxin, the veratrum alkaloids, muscarine, colchicine, khellin, marihuana, and the ergot alkaloids. Radioactive bufotoxin has been prepared [27] by using the tropical toad, Bufo marinus, which is fed on radioactive algae.

The following brief summary of some of the work with radioactive digitoxin illustrates the type of work possible with the aid of these new techniques. Digitoxin is rapidly metabolized to a number of compounds in experimental animals such as the cat, rat, and guinea pig. Whether the cardiac action is attributable to the unchanged digitoxin or to one of the uncharacterized metabolites cannot be determined until they have been isolated and tested, because there is no selective concentration of digitoxin in heart muscle of intact animals.[28] Since the radioactive digitoxin used in these experiments was labeled, in all positions, with carbon 14, all of the metabolites derived from it must conclusively be radioactive; thus, the isolation of these substances is possible. Experiments are also in progress using carbon 14 labeled digitoxin in human subjects.

OTHER RADIOACTIVE ISOTOPES

Radioactive gold is available as gold 198 or gold 199. These isotopes emit both beta and gamma radiation and are used chiefly in the form of colloidal gold injected directly into a tumor mass for local irradiation.[29] Ninety-nine per cent of the gold injected is permanently fixed at the site of injection. Since the half-life of gold 198 is 2.7 days and that of gold 199 is 2.3 days, the radiation continues for a maximum of two to three weeks after fixation. This time is adequate to reduce the activity to less than 1/64 of the original dose. Radioactive gold has also been found useful in chronic leukemia.[30]

Radioactive arsenic has been tried without much success for the treatment of primary and metastatic carcinomas and polycythemia.[30] Radioactive cobalt is being used as a source of gamma radiation in place of radium.

SUMMARY OF ESTABLISHED USES OF RADIOACTIVE ISOTOPES

The principle of selective irradiation of specific tissues through the use of isotopes administered internally already has found clinical application.[31] Radioactive isotopes have been found equal or superior to other forms of therapy for the treatment of chronic myelogenous leukemia, chronic lymphatic leukemia, lymphosarcoma, giant follicular lymphoma, and polycythemia rubra vera. They are also of some value in Hodgkin's disease but are not helpful in acute leukemia and multiple myeloma.[32] Radioactive isotopes are useful in the diagnosis or treatment of some types of carcinoma, especially primary or metastasized carcinoma of the thyroid,[17] breast,[12] or testes.[33] They are the treatment of choice in many cases of hyperthyroidism.[15c] Externally applied, they are of use in the treatment of certain skin lesions.[12]

As diagnostic aids in locating the site of primary tumors or metastases, radioactive phosphorus as sodium phosphate, or radioactive iodine as sodium iodide or as diiodofluorescein,[14] may be used. Radioactive sodium can be used to diagnose disorders of the peripheral circulation and the heart.[19]

The availability of the radioactive isotopes for research furnished investigators with very sensitive new techniques.[34] These new methods make possible the solution of many long-standing problems concerning the metabolism of drugs, since they can be applied where no satisfactory chemical or biologic methods are presently known.

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

R. T. Stormont, M.D., *Secretary.*

Diphtheria and Tetanus Toxoids, Alum Precipitated-U.S.P. (See New and Nonofficial Remedies 1950, p. 435).

Diphtheria-Tetanus Toxoids Combined (Alum Precipitated): 5 cc. vials (five immunizations). Preserved with thimerosal, 1: 10,000. Pitman-Moore Company, Division of Allied Laboratories, Inc., Indianapolis.

Diphtheria and Tetanus Toxoids, Alum Precipitated: 5 cc. (0.5 cc. dose form) and 10 cc. (1 cc. dose form) vials. Five immunizations each. Preserved with thimerosal 1: 10,000. E. R. Squibb & Sons, New York.

Diphtheria Toxoid and Pertussis Vaccine Combined, Alum Precipitated (See New and Nonofficial Remedies 1950, p. 446).

Diphtheria Toxoid, Alum Precipitated, and Pertussis Vaccine Combined: 6 cc. vials (1 cc. dose form). Two immunizations. 15,000 million *H. pertussis* in each cubic centimeter. Preserved with thimerosal 1: 10,000. 7.5 cc. vials (0.5 cc. dose form). Five immunizations. 30,000 million *H. pertussis* in each cubic centimeter. Preserved with thimerosal 1: 10,000. E. R. Squibb & Sons, New York.

Estradial Benzoate-U.S.P. (See New and Nonofficial Remedies 1950, p. 320).

Solution Dimenformon Benzoate in Oil: 1 cc. ampuls. A solution in sesame oil containing 0.1 mg., 0.166 mg., 0.33 mg., 1.0 mg. or 1.66 mg. of estradiol benzoate in each cubic centimeter. Preserved with 0.8% methylparaben and 0.1% propylparaben. 10 cc. vials. A solution in sesame oil containing 0.33 mg. or 2.0 mg. of estradiol benzoate in each cubic centimeter. Preserved with 0.8% methylparaben and 0.1% propylparaben. U. S. Trademark 365,455. Organon, Inc., Orange, N. J.

Estrone-U.S.P. (See New and Nonofficial Remedies 1950, p. 328).

Aqueous Suspension Estrone: 10 cc. vials. A suspension containing 2 mg. of estrone in each cubic centimeter. Preserved with 0.5% phenol. The Bio-Intrasol Laboratories, Inc., Brooklyn.

Solution Estrone in Oil with Benzyl Alcohol 2%: 1 cc. ampuls and 10 cc. vials. A solution in sesame oil containing 1.0 mg. of estrone in each cubic centimeter. Preserved with 0.5% chlorobutanol. The Bio-Intrasol Laboratories, Brooklyn.

Meralluride Injection-U.S.P. (See New and Nonofficial Remedies 1950, page 273).

Solution Mercuhydrin Sodium: 10 cc. vials. A solution of meralluride containing the equivalent of 39 mg. of mercury and 48 mg. of theophylline in each cc. Lakeside Laboratories, Inc., Milwaukee, Wis.

Methapyrilene Hydrochloride (See New and Nonofficial Remedies 1950, p. 32).

Cream Semikon Hydrochloride 2%: 30 gm. tubes and 480 gm. jars. A cream containing 20 mg. of methylpyrilene hydrochloride in each gram. The S. E. Massengill Company, Bristol, Tenn.

Tablets Semikon Hydrochloride 2%: 50 mg. and 100 mg. The S. E. Massengill Company, Bristol, Tenn.

Penicillin for Oral Administration (See New and Nonofficial Remedies 1950, p. 139).

Tablets Crystalline Potassium Penicillin G (Buffered): 250,000 units. Buffered with 0.25 gm. calcium carbonate. Premo Pharmaceutical Laboratories, Inc., South Hackensack, N. J.

Pertussis Vaccine-U.S.P. (See New and Nonofficial Remedies 1950, p. 447).

Pertussis Bacterin (Whole Culture): 1.5 cc. vials (one immunization) and 7.5 cc. vials (five immunizations). 50,000 million *H. pertussis* in each cubic centimeter. Preserved with thimerosal 1: 10,000. Sharp & Dohme, Inc., Philadelphia.

Pertussis Vaccine: 3 cc. (one immunization) and 15 cc. (five immunizations) vials. 30,000 million *H. pertussis* in each cubic centimeter. Preserved with thimerosal 1: 10,000. E. R. Squibb & Sons, New York.

Phenobarbital Sodium-U.S.P. (See New and Nonofficial Remedies 1950, p. 404).

Solution Phenobarbital Sodium with Benzyl Alcohol 2%: 2 cc. ampuls. A solution in propylene glycol containing 0.13 gm. or 0.32 gm. of phenobarbital sodium in each cubic centimeter. Gold Leaf Pharmacal Company, Inc., New Rochelle, N. Y.

Polyamine-Methylene Resin (See The Journal, July 22, 1950, p. 1068).

Powder Exorbin: 1 gm. packets. Ayerst, McKenna & Harrison, Ltd., New York.

Tablets Exorbin: 0.25 gm. Ayerst, McKenna & Harrison, Ltd., New York.

Sodium Folate (See New and Nonofficial Remedies 1950, page 481).

Solution Folvite Sodium with Benzyl Alcohol 1.5%: 10 cc. vials. A solution containing 15 mg. of sodium folate in each cc. Lederle Laboratories, Pearl River, N. Y.

Thiamine Hydrochloride-U.S.P. (See New and Nonofficial Remedies 1950, page 488).

Tablets Thiamine Hydrochloride: 1 mg., 3 mg., 5 mg. and 10 mg. Physicians' Drug and Supply Company, Philadelphia, Penn.

Vitamin B$_{12}$ (See New and Nonofficial Remedies 1950, page 492).

Solution Crystalline Vitamin B$_{12}$: 1 cc. ampuls. A saline solution containing 15 micrograms of vitamin B$_{12}$ in each cc. Kremers-Urban Company, Milwaukee, Wis.

COUNCIL ON PHYSICAL MEDICINE AND REHABILITATION

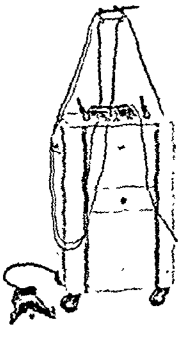
The Council on Physical Medicine and Rehabilitation has authorized publication of the following reports.

HOWARD A. CARTER, *Secretary.*

BOVIE ELECTROSURGICAL UNIT, MODEL O-4, ACCEPTED

Manufacturer: The Liebel-Flarsheim Company, 303 West Third Street, Cincinnati 2.

The Bovie Electrosurgical Unit, Model O-4, is intended for use in all major and minor electrosurgical procedures. It consists of a cabinet that can be rolled about on casters: this has outlets for the cables that run to the operating electrodes. It also bears a cable for the power supply and a cable running to the footswitch assembly. This footswitch controls the current to the operating electrodes.



Bovie Electrosurgical Unit, Model O-4

For operation, the apparatus requires a source of 50 to 60 cycle alternating current at 115 volts. It draws 700 watts of power.

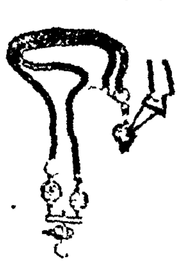
Unpacked, the apparatus measures 67 (height) by 48 by 33 cm. (26½ by 19 by 13 in.) and weighs 48.5 kg. (107 lb.). Packed for shipment it makes a crate measuring 95 by 56 by 70.5 cm. (37½ by 22 by 27¾ in.) and weighing 61 kg. (135 lb.). The foreign shipping weight is 96 kg. The shipping weights include the footswitch, two stainless steel indifferent plates, two chuck handles, endoscopic connecting cord and standard set of surgical electrodes.

Evidence from sources acceptable to the Council indicated that the device was satisfactory in construction and dependable for use in any surgical procedure where electrosurgery is indicated. The Council on Physical Medicine and Rehabilitation voted to include the Bovie Electrosurgical Unit, Model O-4, in its list of accepted devices.

M. S. A. DEMAND PNEOPHORE ACCEPTED

Manufacturer: Mine Safety Appliances Company, Braddock, Thomas and Meade Streets, Pittsburgh 8.

The M. S. A. Demand Pneophore is a device consisting of gas pressure gauges, regulating valves, tubing, and a face mask designed for use in administering oxygen and aerosols to patients. Unpacked, the apparatus weighs 6.8 kg. (15 lb.). Ready for shipment, it makes a package measuring 28 by 51 by 33 cm. (11 by 20 by 13 in.) and weighing 8.6 kg. (19 lb.). The foreign shipping weight is 23.6 kg. (52 lb.). It requires no source of power other than that furnished by the compressed gas in the cylinder.



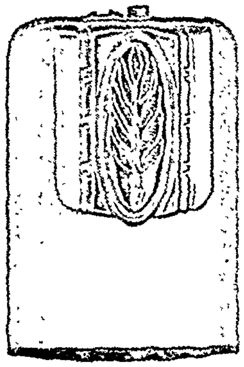
M. S. A. Demand Pneophore

The device is designed to be useful for both "demand" and positive-pressure administration of oxygen. Because of this and because of the claims for therapeutic usefulness in such conditions as pulmonary edema, it appears that medical knowledge is necessary in determining not only which type of operation is adapted to a given case but also what pressure may be applied. Evidence of good construction and dependable performance was obtained from a laboratory acceptable to the Council.

The Council on Physical Medicine and Rehabilitation voted to include the M. S. A. Demand Pneophore in its list of accepted devices with the understanding that it should be used by physicians or under their direct supervision and that a physician should determine how it is to be used and what pressures may be applied in a given case.

DAHLBERG HEARING AID, MODEL D-1, ACCEPTED

Manufacturer: The Dahlberg Company, 2730 West Lake St., Minneapolis 16.



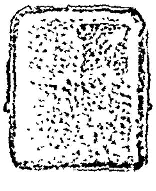
Dahlberg Hearing Aid, Model D-1

The Dahlberg Hearing Aid, Model D-1, was first introduced as the Tonex or Tru-Sonic, Model T-1. It is conventional in electrical design, but remarkable in that the microphone is attached to the clothing clip in such a way as to be outside the wearer's pocket or outer clothing. This clip measures 30 by 37 by 8 mm. The rest of the device measures 62 by 45 by 19 mm. Without batteries, cord, or receiver the device weighs 99 gm. The batteries add 27 gm., and the cord and receiver add 12 gm.

Evidence of satisfactory construction and performance was obtained from sources acceptable to the Council. The Council on Physical Medicine and Rehabilitation voted to include the Dahlberg Hearing Aid, Model D-1, in its list of accepted devices.

PARAVOX HEARING AID, MODEL J (TINY-MYTE), ACCEPTED

Manufacturer: Paravox, Inc., 2056 East Fourth Street, Cleveland 15.



(Tiny-Myte)

The Paravox Hearing Aid, Model J (Tiny-Myte), is an electrical instrument of conventional design and construction, with magnetic receiver. Without switches, clips, etc., it measures 78 by 60 by 16 mm. Without batteries, ear piece or cord it weighs 65 gm. With batteries it weighs 97 gm. Like some other current models, it has no so-called tone control; the manufacturer states that five different magnetic receivers with different frequency response peaks are available. Evidence from sources acceptable to the Council indicated that this device was well constructed, performed as represented by the manufacturer, and satisfied the minimum requirements of the Council for the acceptance of hearing aids. The Council on Physical Medicine and Rehabilitation voted to include the Paravox Hearing Aid, Model J (Tiny-Myte), in its list of accepted devices.

MICRONIC HEARING AID, STAR MODEL, ACCEPTED

Manufacturer: Micronic Company, 727 Atlantic Avenue, Boston 11.

The Micronic Hearing Aid, Star Model, is an electrical hearing aid with magnetic receiver and crystal microphone, conventional in arrangement, design and parts. Excluding hinges, switches, etc., it measures 81 by 45 by 18 mm. Without batteries, ear piece or cord it weighs 66 gm. With batteries it weighs 94 gm.

Evidence from sources acceptable to the Council indicated that this device was well constructed, performed as represented by the manufacturer, and satisfied the minimum requirements of the Council for acceptance of hearing aids. The Council on Physical Medicine and Rehabilitation voted to include the Micronic Hearing Aid, Star Model, in its list of accepted devices.

RADIATION MYELITIS

During intensive x-ray therapy of structures close to the brain or spinal cord, sufficiently large amounts of radiation may be received by the brain or cord to produce serious damage.[1] That this complication occurs more frequently than is generally realized is indicated by several studies made in the last few years. Boden,[2] for example, found five fatal and five nonfatal cases of radiation myelitis of the cervical cord in a series of 161 patients who received x-ray therapy for malignant tumors of the nose, mouth, pharynx, or cervical lymph nodes. Because of the long latent period between the irradiation and the appearance of symptoms, the cause of the condition was often not recognized initially. Frequently, the patient, discharged by the radiologist during this interval, was seen by a physician who was unaware of the technic of irradiation or of its implications. Symptoms were usually ascribed, without proof, to metastases from the original tumor, and only at autopsy was the true nature of the lesion discovered. The initial symptoms in every case were numbness and tingling in the hands or feet precipitated by flexion or extension of the neck and often associated with pain in the neck and shoulders. In a few cases these symptoms were transient, disappearing in three to nine months. In the remainder the paresthesias were followed by weakness or spastic paralysis of one or more extremities and later by bowel or bladder dysfunction. In the fatal cases there was intercostal paralysis. Death resulted eventually from bronchopneumonia or ascending urinary tract infection. When the number of roentgens received incidentally by the cervical cord during the irradiation therapy of these patients was calculated from their records, it was discovered that most of them had received a higher dose than was intended. Sometimes this was due to overlapping of fields of irradiation from multiple portals and at other times to the physician's miscalculation of radiation factors or failure to elicit a history of previous irradiation to the neck for other purposes.

Subsequently Boden [3] reported seven cases of fatal radiation damage to the brain stem following x-ray therapy of malignant tumors of the middle ear, pharynx, or parotid gland. He found that this catastrophe occurred in the startling proportion of 25% of the patients treated by beam-directed techniques in which multiple small fields were centered on the tumor. The cranial nerve palsies, ataxia, and hemiplegias that appeared 11 to 20 months after irradiation in the older patients were usually attributed to cerebrovascular accidents until autopsy proved the error of this diagnosis. As a result of his dosage calculations in these two series of patients, Boden concluded that the limit of tolerance of the central nervous system is 3,500 to 4,500 r, depending on the size of the fields used. He warned that, with doses above this level, symptoms are likely to occur.

Prior to Boden's study Ahlbom [1b] observed four fatal cases of radiation myelitis of the cervical cord in a series of 235 cases of cancer of the hypopharynx treated with x-rays or radium, and Stevenson and Eckhardt [4] reported a fatal case in which the cervical cord received 6,000 to 8,000 r during intensive radiation therapy for lymphoepithelioma of the nasopharynx. Radiation myelitis of the thoracic portion of the spinal cord occurred in a patient reported by Smithers, Clarkson, and Strong,[5] who received a depth dose of 5,800 r in 39 days for carcinoma of the esophagus. Similar involvement of the lumbosacral segment of the cord was recorded by Greenfield and Stark [6] in three patients out of a series of 180 following irradiation of retroperitoneal nodes for carcinoma of the testis. The spinal cords of these patients received between 4,500 and 5,500 r.

In all these cases the delayed onset of the symptoms and the microscopic findings at autopsy suggested that the roentgen rays affected primarily the blood vessels rather than the neurones and that the eventual neurologic lesions were the result of gradual impairment of blood supply. This is in keeping with the concept that blood vessels are much more susceptible to radiation damage than is nerve tissue. The lesions of radiation myelitis can be distinguished clinically from those of metastases to the spine or cord by the absence of roentgenographic changes in the vertebrae and the absence of changes in the spinal fluid (with the exception of an occasional elevated protein level) in the former. Prevention of catastrophes of this kind, according to Boden, depends on the modification of radiotherapeutic techniques so that as far as is possible, radiation of the central nervous system is avoided. When it is necessary to irradiate tumors situated near the spinal cord or brain, the depth dose received by these structures should routinely be estimated and should be kept as low as possible, preferably below 3,500 to 4,500 r.

SUBCLINICAL INFLUENZA

Confirmation of the current theory of subclinical infection is reported by Kalter[1] of State University, Syracuse, N. Y. This is based on a study of the development of influenzal antibodies in eight students engaged in research with influenza virus. Three stains of virus (PR8, Lee, and Fm-1) were used in their investigations, which consisted in inoculations, harvesting and titrations of these strains over a period of three to four months. Hemagglutination-inhibition titers were taken of the serums of these eight students before this research was begun. Titers were also taken after two months of laboratory exposure and at the end of their work. Control titrations were made of the serums of 57 fellow students not engaged in this research.

The initial serum samples of all students had antibody titers varying from 40 to 640 units. The titers were highest against the Lee strain, presumably owing to a previous Syracuse influenza B epidemic. By the end of the test period, six of the eight students in the research group showed a fourfold to a thirtyfold increase in antibody titer against all three strains. The remaining two students of this group showed similar increases to but one or two of the three strains. There was no demonstrable antibody increase in the control group of 57 students. None of the test group had any clinical symptoms resembling influenza during the test period. The increased antibody titer was thus presumably due to subclinical or inapparent infection with one or more (usually all three) of the test viruses.

THERMAL GRADIENTS IN THE VASCULAR SYSTEM

Recent data on intracardiac and deep intravascular temperatures are of interest, since the mechanisms that normally maintain temperature within narrow limits are not yet well understood. Horvath, Rubin, and Foltz[1] measured the temperature in various blood vessels and tissues in the anesthetized dog by means of thermocouples fitted into plastic catheters and reported the presence of thermal gradients in the vascular tree, indicative of sites of increased heat production. Employing similar techniques, Eichna and his associates[2] measured the temperature in the right side of the heart, in the deep vessels leading to the right side of the heart, in the femoral artery, and in the rectum in 24 afebrile and five febrile hospitalized subjects. Temperatures in the right side of the heart, pulmonary artery, and femoral artery were found to be equal and consistently less than that in the rectum. In afebrile patients, the average difference between rectal temperature and that of the right side of the heart was 0.25 C.; in febrile patients differences as great as 0.8 C. were noted, the differences being greater in patients with higher fevers. The temperatures in the superior vena cava and in the femoral artery were approximately equal to those of the right atrium, while progressively lower temperatures were recorded as the thermocouple was moved from the right atrium into the superior vena cava and into the subclavian vein. On the other hand, the temperature rose as the thermocouple passed from the subclavian into the common jugular vein, and at the level of the jugular bulb it equaled the rectal temperature. The temperature of the hepatic vein blood also equaled that of the rectum.

Clinically, body temperature is usually determined by measurement of the temperature in the mouth, rectum, axilla, or groin. The studies of Horvath, of Eichna, and of Bazett[3] and their associates offer evidence of a complex pattern of local areas of heat production and heat loss within the body; hence a single temperature measurement gives an inadequate picture of the temperature in other parts of the body. If maintenance of thermal homeostasis depends on the temperature of the blood reaching the hypothetical temperature-regulating center in the hypothalamus, intracardiac and femoral arterial temperatures should be of considerable significance, since the temperature of the blood entering the critical tissue is more likely to be indicated by these temperatures than by any other measurement now available.

UTILIZATION OF NONSPECIFIC NITROGEN

It is well known that the rat will grow and maintain its nitrogen balance on rations whose nitrogen content is derived exclusively from mixtures of the so-called essential amino acids. The usual protein sources, on the other hand, are made up of about 20 different amino acids, and the eight amino acids which Rose found essential to maintain nitrogen balance in man compose only about 40 to 50 per cent of the protein.

It is of interest to determine whether the nonessential amino acids are necessary for the optimum utilization of the essential ones and, also, to what degree the essential amino acids can be replaced by nonspecific nitrogen donors. These problems were recently studied by Frost and Sandy,[1] using the method of repleting rats that had been on a protein-deficient diet, a procedure developed earlier by Cannon. These investigators had shown that there was poor repletion of rats fed a mixture of the essential amino acids minus arginine, but, if isonitrogenous diets were used in which one-fifth to one-third of the nitrogen was replaced by arginine, glutamic acid, ammonium acetate, or diammonium citrate, a marked increase in appetite and body weight of the animals occurred. More striking, the weight increase of these animals compared favorably with that of rats receiving protein of high biologic value. For the rat, this work would indicate that at least 20% of the total nitrogen should be in the form other than essential amino acids to promote maximum utilization by the tissues. The actual form of this extra nitrogen appears to be nonspecific, and any ammonium salt or nitrogenous substance that, in the process of metabolism, gives rise to ammonia can be used. Work of this type is of considerable interest, since such data are essential to the preparation of amino acid mixtures for intravenous alimentation which will provide most efficient utilization of the injected nitrogen.

ORGANIZATION SECTION

STUDENT A. M. A.

Russell F. Staudacher, formerly of Lansing, Mich., who joined the American Medical Association and its Council on Medical Service May 1, 1951, has been named to a new and dual capacity with the organization. On July 1, he assumed the duties of executive secretary for both the Student American Medical Association and the American Medical Education Foundation. Prior to his association with the American Medical Association, Mr. Staudacher served as Associate Public Relations Counsel for the Michigan State Medical Society for several years. He also acted as public relations consultant to the Lansing (Mich.) Board of Education.

Immediately after military service he worked for the St. Louis public relations counseling firm of Frank Block and Associates. A World War II veteran with nearly four years' service with the Air Force in the European Theater in public relations, Staudacher also served on the USAAF public relations staff assigned to the 1945 atomic bomb tests on Bikini Atoll. He entered the Reserve Corps in 1945 as a major. Mr. Staudacher graduated from Alma (Mich.) College with a bachelor of arts degree and life teacher's certificate. He is married and has one son.

MEDICAL EDUCATION AND HOSPITALS

From time to time correspondence received at American Medical Association headquarters offices will be reproduced with their replies when it is believed that this correspondence will be of general interest to the readers of THE JOURNAL.—ED.

QUESTION.—*A hospital has had an application for appointment to their intern staff from a graduate of a foreign medical school which is not on the Council's list. May this man be appointed without jeopardy to the hospital's approved status?*

ANSWER.—Yes. Graduates of foreign medical schools may be appointed at the discretion of the hospital without prejudicing the hospital's approval for intern training. Lacking adequate information regarding the professional training which these schools provide, however, the Council does not assume any responsibility for evaluation of the graduate's credentials.

QUESTION.—*A hospital has been approved by the Council as offering satisfactory training in general surgery in preparation for a residency in a surgical specialty. After having completed one year of training in this hospital, the resident decides he wants to qualify for examination in general surgery. Will he receive credit by the American Board of Surgery for the year of training he has had?*

ANSWER.—No. Programs of this type have been approved to provide facilities for training in general surgery for residents who are qualifying for examination by one or another of the surgical specialty boards; e. g., American Board of Urology. Training in general surgery of less than three years' duration is accepted by the American Board of Surgery only if the program is integrated with that of a hospital which is fully approved (*J. A. M. A.* **142**:1216 [April 15] 1950).

QUESTION.—*How many x-ray and fluoroscopic machines are there in the United States?*

ANSWER.—This office does not have information on the number of x-ray and fluoroscopic machines in the United States, but according to our records a total of 5,386 registered hospitals have x-ray departments. Many of these, of course, have several x-ray units for roentgenographic and fluoroscopic procedures, besides studies and low and high voltage x-ray therapy.

We have also been informed that the publishers of *Modern Medicine* (84 South 10 St., Minneapolis) made a study some time ago of x-ray facilities in the medical and hospital fields. Their report indicated that x-ray equipment was owned by 5,170 hospitals and 32,250 physicians in the United States.

QUESTION.—*What are the qualifications necessary for a hospital staff appointment?*

ANSWER.—In general, it is required that the medical staff of a hospital should be limited to graduates in medicine who are properly qualified by training, licensure and ethical standing and are proficient in the fields of practice to which they devote themselves.

It has been further stated, however, that hospital staff appointments should depend on the qualifications of physicians to render proper care to hospitalized patients, as judged by the professional staff of the hospital, and not on certification or special society membership. Qualifications, therefore, are directly related to the amount of training and experience that individual physicians have obtained in their respective fields.

STATE LEGISLATION

California

Bills Enacted.—H. R. 155, was adopted June 22, 1951. It provides for the creation of an Interim Committee on Public Health to, among other things, study and analyze all matters relating to or affecting **public health** including needed revision of any and all laws in any way bearing upon the subject. H. R. 194 was adopted June 22, 1951. It provides for the creation of an Interim Committee on Finance and Insurance to study, among other things, **voluntary plans of hospital and/or health insurance** or plans operating under provision of the law to protect persons from the high costs of sickness and accidents in the state and other unregulated plans purporting to operate under existing provisions of law, and the need for regulation under existing laws or the enactment of regulatory legislation. H. R. 195 was adopted June 22, 1951. It provides for the creation of an Interim Committee on Finance and Insurance to study and analyze all facts relating to the furnishing of **pre-paid medical, surgical, hospital and other related services,** especially by unlicensed, unregulated and nonprofessional persons and organizations. S. R. 187, was adopted June 23, 1951. It creates an Interim Committee on **Narcotics and Hypnotics** to ascertain, study and analyze all facts relating to narcotics and hypnotics including the operation, effect, administration, enforcement and needed revision of all laws bearing upon the subject of the committee's duties. S. R. 214, was adopted June 23, 1951. It creates an Interim Committee to study and analyze all facts relating to a **shortage of nurses.** S. 731, has become Chapter 1201 of the Laws of 1951. It amends the health and safety code by requiring hospitals to keep a record of the **administration of hypnotic drugs,** including the amount given, the type, the date, and the name and address of the person to whom administered. S. 820 has become Chapter 1149 of the Laws of 1951. It amends the law relating to **narcotics** by making it a felony to sell, give away or prepare for sale or administer any narcotic to a minor.

Pennsylvania

Bills Introduced.—H. 1449 proposes to amend the law relating to mental illness, mental defect, epilepsy and inebriety by defining the word **"qualified physician"** as including osteopath. H. 1497 proposes general amendments to the **mental health act.** H. 1510 relates to the supplying of **insulin to diabetic pupils** in the public schools. H. 1524 proposes an appropriation of five hundred thousand dollars ($500,000) to the Department of Health for a study of **alcoholism** and treatment and rehabilitation of alcoholics. S. 746 proposes to require water companies to **treat water with sodium fluoride** when the governing body of any city, borough, town or township has, by ordinance or resolution, determined that the water supply thereof should be so treated.

Texas

Bills Enacted.—H. C. R. 108, was adopted June 8, 1951. It resolves that the House go on record as requesting this Board of State Hospitals and Special Schools to take the necessary steps to meet the **minimum standards** required in order to qualify the said **Hospitals and Special Schools** operated by the State of Texas to the necessary standards for residency, intern and nurses training programs so that the patients of the said Hospitals and Special Schools be given the highest type of medical care and treatment possible. S. 290 was approved June 15. It amends the medical practice act by authorizing the issuance of **temporary licenses to practice medicine** which shall be in effect until the next regular meeting of the board of examiners. S. 291 was approved June 15, 1951. It amends the basic science act by permitting the issuance of **temporary licenses** to be effective until the next regular meeting of the board. S. 295 was approved June 15, 1951. It makes it unlawful to sell or deliver any **barbituric acid,** amphetamine and desoxyephedrine except by a pharmacist upon an original prescription of a physician, dentist, chiropodist or veterinarian.

This summary was prepared by the Bureau of Legal Medicine and Legislation.

MEDICAL NEWS

ARKANSAS

Rural Health Conference.—The rural health committee of the Arkansas Medical Society, with the assistance of the Farm Bureau Federation, the Arkansas Dental Association, the Council of Home Demonstration Agents, and the Extension Service of the University of Arkansas, is sponsoring a conference in Little Rock August 9-10. The purpose is to help the medical profession and the rural citizens to assess their individual responsibilities in the solution of Arkansas' rural health problem.

CALIFORNIA

Retiring Professors Honored.—Three retiring members of the faculty of the University of California School of Medicine, San Francisco, were honor guests at the banquet of the school's alumni association June 15. They are Dr. Edwin I. Bartlett, associate clinical professor of surgery and pathology; Dr. LeRoy H. Briggs, William Watt Kerr Clinical Professor of Medicine, and Dr. Howard C. Naffziger, professor of neurological surgery and chairman of the department.

Personals.—Dr. Jacob C. Geiger, director of public health, City and County of San Francisco, recently received the Honorary Knighthood of the Royal Order of Dannebrog.——Dr. Edwin E. Kerr, assistant in surgery, University of California Medical School, San Francisco, has been awarded the $250 Helmut William Fesca Prize for 1951 as a member of the resident staff of the division of surgery who has done outstanding work during the last year. The prize was established by various donors in memory of Dr. Helmut William Fesca, who died July 27, 1944.

FLORIDA

State Medical Election.—At the annual meeting of the Florida Medical Association in Hollywood, April 22-25, Dr. David R. Murphey Jr., Tampa, was installed as president. Elected officers include Dr. Robert B. McIver, Jacksonville, president-elect, and Dr. Samuel M. Day, Jacksonville, secretary-treasurer.

GEORGIA

Dr. Shanks Honored.—Dr. Edgar D. Shanks, who has practiced medicine in Atlanta for 25 years, was presented a silver service July 1 by more than 50 friends in appreciation of his "faithful and loyal service to medicine in Georgia." Dr. Shanks served 16 years as secretary-treasurer of the Medical Association of Georgia and as editor of the association's journal. He also has served on numerous committees of the Fulton County Medical Society and was elected to its presidency in 1935.

INDIANA

Narcotic Violation.—Dr. Joseph A. Wall, Wabash, pleaded guilty at South Bend to a violation of the federal narcotic law and on May 14 was sentenced to a term of three years. The sentence was suspended and he was placed on probation for a period of five years.

Rural Health Conference.—This conference will be held July 31 at Purdue University, Lafayette, under the sponsorship of the committee on rural health of the Indiana State Medical Association in cooperation with the Agricultural Extension Service of the university. Out-of-state speakers include Dr. Herman N. Bundesen, commissioner of health of Chicago; Dr. Josiah J. Moore, Chicago, member of the National Brucellosis Committee, who will speak on "The Nation and Brucellosis," and Dr. George F. Bond, Bat Cave, N. C., whose subject will be "Here's Health the American Way." There will be a panel discussion on brucellosis. In the afternoon Mr. Robert Yoho of the Indiana State Board of Health will be moderator for a panel discussion, "Using Your Community Health and Medical Services to the Best Advantage."

KENTUCKY

General Practitioners Elect Officers.—At a meeting of the Kentucky Academy of General Practice in Louisville June 3 Dr. Richard R. Slucher, Buechel, was installed as president; other officers are Dr. Joe M. Bush, Mt. Sterling, president-elect; Dr. Keith P. Smith, Corbin, vice president, and Dr. David G. Miller Jr., Morgantown, secretary-treasurer.

Personals.—Dr. Frank M. Gaines Jr., Louisville psychiatrist, has been appointed state director of hospitals and mental hygiene succeeding Dr. Addie M. Lyon, now superintendent of the Central State Hospital, Lakeland. Dr. Gaines formerly held the position of clinical director of Norton Psychiatric Clinic, Louisville.——Dr. Lucius E. Smith, Louisville, has resigned as executive secretary of the Kentucky Tuberculosis Association. Dr. Smith was paid tribute at a luncheon and a dinner in Louisville April 27.——Dr. Robert Lich Jr., head of the urology department, University of Louisville School of Medicine, has been named a member of the Society of Genito-Urinary Surgeons. He is the only Kentucky urologist ever admitted to this organization.

MASSACHUSETTS

University News.—Harvard University, Boston, has allocated two-thirds of the $300,000 Ford Foundation grant it received last October to its medical school for a five-year study of the physiological and psychological effects of adrenal hormones.

Award Alvarenga Prize.—On July 14 the College of Physicians of Philadelphia awarded the Alvarenga Prize for 1951 to Dr. George W. Thorn, Hersey Professor of the Theory and Practice of Physic, Harvard Medical School, Boston, for his contributions on the role of the adrenal cortex in health and disease. The prize was established by the will of Pedro Francisco DaCosta Alvarenga of Lisbon, Portugal, an associate fellow of the college, to be awarded annually by the college on the anniversary of the death of the testator.

MINNESOTA

State Board Regulates Children's Camps.—Regulation of children's camps in Minnesota was made the responsibility of the state board of health by the 1951 state legislature. Every summer between 200 and 300 camps for children are conducted in Minnesota. Some are run by private individuals; others are operated as a public service by churches or by youth organizations. The Minnesota Camping Association, with membership representing many of the camps and youth organizations, was responsible for introduction of the new legislation. The state board of health is authorized to issue yearly free permits for the operation of children's camps, and these are already being issued. State department of health personnel will visit the camps annually and will inform the operators of any failure to protect the health or safety of children.

Dr. Bittner Wins Cancer Award.—John J. Bittner, *Ph.D.*, director of the division of cancer biology of the University of Minnesota, is the first winner of the Comfort Crookshank Award for Cancer Research, an honor presented through the Middlesex Hospital Medical School in London, England. In September Dr. Bittner will go to London to receive the silver medal award and the monetary grant of 230 English pounds ($644) which goes with it. He will deliver a lecture on his cancer research at the medical school. The award, from funds donated by the late Bessie C. Crookshank, will be presented triennially to a scientist who has made valuable contributions to cancer research. Dr. Bittner is past president of the American Association for Cancer Re-

---

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

search and the winner of the 1950 medal of the American Cancer Society. He was a member of the Medical Teaching Mission to Austria in 1947, sponsored by the Unitarian Service Committee and the World Health Organization. In 1947 Dr. Bittner was the official United States delegate to the Fourth International Cancer Research Congress.

MISSOURI

Rehabilitation Institute Moves to New Quarters.—The Vocational Rehabilitation Institute, Kansas City, has moved to a three-story building recently acquired as its permanent home. The institute is operated by 17 social agencies. Its medical policies are under the direct control of the Jackson County Medical Society through the medium of a medical advisory committee. On the first floor are the curative workshops, speech department, recreational space, and a layout for the projected therapeutic pool. Physical therapy and occupational therapy departments are on the second floor. The enlarged quarters made possible the addition of the ceramics and printing departments. The National Foundation for Infantile Paralysis is extending its scope to include services at the institute.

NEW JERSEY

Personal.—Dr. Henry H. Kessler, medical director of the Kessler Institute for Rehabilitation, West Orange, recently received the Edward J. Ill Award for 1951 from the Academy of Medicine of Northern New Jersey.

Cancer Grant to Rutgers.—The Damon Runyon Memorial Fund for Cancer Research has made a grant of $20,000 to Rutgers University bureau of biological research, New Brunswick, to continue and expand its study of chemical controls for cancer. The fund has made two other grants to the bureau: $10,000 in 1949 toward chemo-therapeutic studies and $5,000 in 1950 for the study of carcinogens.

Award in Orthopedics.—The New Jersey Orthopaedic Society offers an award of $100, open to all residents and interns in the State of New Jersey, for the best paper on an orthopedic or closely related subject. The paper selected will be read by the author at the spring meeting of the society in 1952. Papers are to be submitted on or before Jan. 15, 1952, to the secretary, Dr. Philip Willner, 852 S. 11th St., Newark 6.

NEW YORK

Dr. Campbell Named Dean at Albany.—Dr. James A. Campbell, assistant professor of medicine at the University of Illinois College of Medicine, Chicago, has been appointed dean of Albany Medical College, effective Sept. 1. Dr. Robert S. Cunningham, dean since 1937, will be given new responsibilities as executive director of the Albany Medical Center Council, a position he has held since May 1950. Dr. Campbell, a graduate of Harvard Medical School, Boston, in 1943, was appointed in 1946 executive officer of the medical division of the clinical research section at the Army Chemical Center, Edgewood Arsenal, Md. In 1947 he was named Harvey Cushing Fellow at Johns Hopkins Hospital and Medical School in Baltimore. He joined the staff of Presbyterian Hospital, Chicago, as assistant attending physician in 1948. Last year he was appointed associate attending physician and is in charge of the clinical teaching of medicine there. Dr. Campbell is 33 years old.

New York City

Dr. Rabinoff to Direct Department.—Dr. Sophie Rabinoff, since 1947 associate professor in public health at New York Medical College, Flower and Fifth Avenue Hospitals, has been appointed professor and director of the department of public health and industrial medicine. She has been connected with the Department of Health of New York City since 1934.

Changes in Hospital Directors.—Dr. Christopher F. Terrence has been appointed director of Rochester State Hospital, and Dr. Richard V. Foster, director of Gowanda State Hospital, effective July 1. Dr. O. Arnold Kilpatrick, former director at Rochester, has been transferred to Hudson River State Hospital, and Dr. Charles Buckman, former director at Gowanda, has been promoted to assistant state commissioner of mental health.

Personals.—Dr. Morton L. Levin, director of the office of medical services in the state department of health, who has been on leave of absence for a year at American Medical Association headquarters in Chicago, directing the program of the Commission of Chronic Illness, has returned to the department.——Dr. Walter Levy has been elected president of the Alumni Association, New York University College of Medicine, a unit of the New York University-Bellevue Medical Center.

NORTH CAROLINA

Critical Nursing Shortage.—Duke Hospital, Durham, may have to close some of its beds or turn away some patients unless the current nursing shortage can be met, according to F. Ross Porter, the superintendent. The shortage of nurses at Duke has reached "critical proportions," he said, mainly because the hospital is now admitting the largest number of bed patients in its 20-year history.

Annual Medical Symposium.—The fifth annual medical symposium sponsored by the New Hanover County Medical Society will be held at Wrightsville Beach August 24. Among the principal speakers will be:

Hans Selye, Montreal, Canada, Cortisone and Corticotrophin (ACTH).
Charles F. McKhann, Cleveland, Convulsive Disorders.
John Pemberton, Rochester, Minn., Carcinoma of the Thyroid.
Isaac S. Tassman, Philadelphia, Fundus Changes in Vascular Disorders.
Robert W. Johnson Jr., Baltimore, Arthritis.

Officers of the society are Dr. Elbert C. Anderson of Wilmington, president, and Dr. William F. Barefoot of Wilmington, secretary.

OHIO

Narcotic Violation.—Dr. Louis R. Effler, Toledo, pleaded *nolo contendre* in the United States District Court at Toledo to a violation of the federal narcotic law and on June 15 was fined $200 and costs.

Dr. Sherry Succeeds Dr. Mirsky.—Dr. Solomon Sherry, New York, has been appointed director of the May Institute for Medical Research of the Jewish Hospital Association and assistant professor of the department of internal medicine at the University of Cincinnati School of Medicine, succeeding Dr. I. Arthur Mirsky, who has been made professor of clinical science and professor of research psychiatry at the University of Pittsburgh School of Medicine. Dr. Sherry had been assistant professor of medicine at New York University College of Medicine and assistant visiting physician at Bellevue Hospital, New York. During World War II he served in the medical corps of the army as flight surgeon with the rank of major and was awarded the U. S. Army Typhus Commission Medal for work on typhus control in Bavaria.

PENNSYLVANIA

Society News.—The third annual meeting of the Pennsylvania Academy of General Practice was held in Bedford May 25-27. Among the speakers were Drs. Charles P. Bailey and William A. Jeffers, both from Philadelphia; Dr. Philip Thorek, Chicago, and Dr. Roger B. Scott, Cleveland. New officers elected were as follows: Dr. Benjamin Schneider, Danville, president; Dr. Harry K. Marcy Jr., Pottstown, vice president; Dr. Anthony T. Merski, Erie, president-elect, and Dr. Horace W. Eshbach, Drexel Hill, secretary-treasurer.——The annual meeting of the Reading Eye, Ear, Nose and Throat Society was held June 20 at the Reading Hospital in West Reading. Principal speakers included the following:

Ramon Castroviejo, New York, Modern Concepts in Glaucoma Surgery, and Methods and Techniques in Ocular Surgery.
Benjamin H. Shuster, Philadelphia, Cranial Nerves in Otolaryngology.
Charles H. La Clair Jr., Norristown, Pa., Spontaneous Intramaxillary Hemorrhage.

Officers elected for the ensuing year include Dr. Harold L. Strause, president; Dr. J. Van Dyke Quereau, president-elect; Dr. Philip R. Wiest, treasurer, and Dr. Benjamin F. Souders, secretary.

Philadelphia

Personals.—Dr. Chevalier Jackson, professor of laryngology and broncho-esophagoscopy at Temple University School of Medicine, is president of the Philadelphia Civic Opera Company. ——Dr. Charles L. Brown, dean of the Hahnemann College and Hospital of Philadelphia, has been appointed as chief consultant in internal medicine on the board of central office consultants of the Veterans Administration.

Fellowship in Ophthalmology.—A two-year fellowship in ophthalmology has been added to the list of postgraduate training opportunities of the Woman's Medical College. The fellowship is under the direction of Dr. Eunice LeBaron Stockwell. The program will be carried out in the Hospital of the Women's Medical College of Pennsylvania, the Woman's Hospital, Pennsylvania School for the Deaf, and the Childrens' Heart Hospital. The first fellow is Dr. Marilyn Rigg of Los Angeles.

Pittsburgh

Studies on Inheritance.—Dr. Ching Chun Li, newly appointed research fellow in biostatistics, will conduct studies on inheritance in relation to public health problems at the Graduate School of Public Health, University of Pittsburgh. Dr. Li was graduated from the University of Nanking, China, in 1936. From 1946 to 1950, after graduate work at Cornell, University of Chicago, Columbia University, and North Carolina State College, he was professor and head of the department of agronomy at the National Peking University in Peiping, China. He left this position when the Chinese Communist government forbade the teaching of the Mendelian principles of heredity because they are unacceptable to communist ideology. Dr. Li's return to this country was made possible through the efforts of the Genetics Society of America.

TENNESSEE

State Medical Election.—Dr. Ernest G. Kelly, Memphis, was installed as president of the Tennessee State Medical Association at its recent annual meeting. Officers elected include Dr. Daugh W. Smith, Nashville, president-elect; Dr. Charles C. Trabue IV, Nashville, speaker of the house, and Dr. Rudolph H. Kampmeier, Nashville, secretary-editor.

Dr. Overman Directs Laboratory.—Richard R. Overman, Ph.D., Knoxville, has been appointed director of the laboratory of clinical physiology at the University of Tennessee, Knoxville. This laboratory is a portion of the Institute of Clinical Investigation, which has recently been established as an adjunct of the Medical Units of the university and the John Gaston Hospital. The new laboratory is intended to perform basic physiological determinations on the hospital patients and to promote clinical research programs. Dr. Overman has been associate professor of physiology in the University of Tennessee School of Biological Sciences since 1948.

VIRGINIA

Personals.—Dr. Claude C. Coleman, professor of neurological surgery and chairman of the department of the Medical College of Virginia, Richmond, has resigned from his teaching duties after 42 years of service, but will continue to do consulting work at the college after his resignation becomes effective July 1. The honorary degree of doctor of science was conferred on Dr. Coleman at the commencement exercises June 5.——Dr. William R. Bond, Richmond, has been made director of clinical research for the A. H. Robins Co., Inc., of Richmond. He is a lecturer in physiology at the Medical College of Virginia.

Visiting Professor to African University.—Dr. Sydney W. Britton, professor of physiology, University of Virginia, Charlottesville, has been appointed visiting professor of endocrinology at the University of Nigeria and will leave for Africa in February, 1952. Announcement of the award of the visiting professorship was made by the Department of State under terms of the Fulbright Act. While in Africa Dr. Britton will continue his investigations on endocrine involvement in the maintenance of the upright position, using primates available in the region. He will be on leave of absence from the University of Virginia during the second semester and will retire at the end of the year after 24 years of service.

WEST VIRGINIA

Personals.—Dr. Thomas L. Harris, Parkersburg, a past president of the West Virginia State Medical Association, has been appointed to the board of governors of West Virginia University for a term ending June 30, 1960.——Dr. George F. Evans, Clarksburg, has been reappointed a member of the medical licensing board for the term ending June 30, 1956. He has been on the board since its creation by the legislature in 1949.——Dr. Delivan A. MacGregor, Wheeling, has been appointed a member of the state board of health for the unexpired term of Dr. Robert J. Reed, also of Wheeling, who resigned late in June. Dr. MacGregor's term will expire June 30, 1956.

Osteopathy a Limited Practice.—The attorney general of West Virginia on June 18 handed down an opinion that affects practice in West Virginia by osteopathic physicians and surgeons. In the opinion, which was written by T. D. Kauffelt, assistant attorney general, it was held that "osteopathic physicians and surgeons are entitled to the same rights and privileges as doctors of medicine in the treatment of cases only to the extent that their treatment remains within the field of osteopathy as defined by the legislature." The opinion ends with the statement that such treatment "is generally considered to exclude the administration of drugs and operative surgery." The matter was officially laid before the attorney general by Dr. Newman H. Dyer, state director of health, acting at the direction and on behalf of the state board of health and the medical licensing board. These two state agencies had previously been requested by the council of the West Virginia State Medical Association to seek an opinion from the attorney general concerning the legality of practice by osteopathic physicians of the same type of medicine and surgery now practiced by doctors of medicine.

GENERAL

Award in Otology.—Theodore H. Bast, Ph.D., of the University of Wisconsin Medical School, Madison, and Barry J. Anson, Ph.D., of Northwestern University Medical School, Chicago, received jointly the award of merit of the American Otological Society at its annual meeting in Atlantic City, N. J., May 12. Each received a silver medallion and a check for $500. Drs. Bast and Anson have been associated for many years in a special study of embryology and anatomy of the temporal bone and the ear. Much of their work, supported by the central bureau of the American Otological Society, has been summarized in a book "The Temporal Bone and the Ear," published in 1949. This is the society's second award for outstanding service in research in otology and in the interest of encouraging research on the problems of impaired hearing.

WHO Ships Mobile Health Units.—Three mobile health units, gifts from the World Health Organization to the governments of Jordan, Syria, and Lebanon, have been shipped from Alexandria, Egypt, to Beirut, Lebanon. The gift to Jordan is a $9,600 mobile dispensary built in Egypt on a bus chassis. The body contains a clinic and a laboratory as well as a dispensary. The unit will be used in desert and semidesert areas to carry medical and clinical services to remote places where no medical aid is available. The gifts to Syria and Lebanon are mobile public health education units. They contain posters, film projectors for outdoor showings, and public address systems with amplifiers and loudspeakers. On arrival in Beirut all three units will be handed over to the public health services concerned.

Committee Seeks More Exact Causes of Blindness.—The Committee on Statistics of the Blind at a recent meeting voted to make minor changes in the official classification of causes of blindness in order to obtain more complete statistics. It seeks more exact data on the number of premature infants becoming blind as a result of "retrolental fibroplasia," which has appeared only in the last few years, as well as more complete data on blindness from onchocerciasis and toxoplasmosis, parasitic diseases. The committee was first organized in 1930, and the classification on causes of blindness worked out by the group has since been adopted as standard throughout the world. Present members of the committee are Ralph G. Hurlin, Ph.D., New York, chairman, and Drs. Conrad Berens, Marta Fraenkel, and Raymond L. Pfeiffer of New York; Gabriel Farrell, D.D., Watertown, Mass.; Dr. Trygve Gundersen, Boston, and Dr. Carl E. Rice and Anne E. Geddes, Washington, D. C.

Art Association Awards.—Among the winners of the American Physicians Art Association exhibit held in Atlantic City, N. J., June 11-15 were Dr. Sol Fineman, New York, who won the Helser Cup for Yankee Ingenuity, and Dr. Richard H. Gwartney, San Bernardino, Calif., the Helser Second Cup. The Popularity Trophy was won by Dr. Leonard B. Fauguier, Jersey City, N. J. Thirteen first prizes were awarded in the advanced and beginners classes of media. Officers of the association for the coming year are Dr. Meyer M. Melicow, New York, president, and Dr. Francis H. Redewill, San Francisco, secretary-treasurer.

Cancer Mortality.—Encouraging indications of a decline in cancer mortality are reported by statisticians of the Metropolitan Life Insurance Company, who base their findings on the postwar experience of the company's millions of industrial policyholders. According to the report, for the accessible sites as a group, declines in the death rate for both men and women were recorded from 1946-47 to 1949-59, men by 2.4% and women by 7.2%. There was a reduction in female mortality from almost all the accessible specific types of cancer. In the case of the inaccessible sites as a whole, the death rate among women declined 1.1%, but, on the other hand, that among men showed an increase of 4%. However, both sexes showed decreases for such specific sites as the stomach, intestines, other digestive organs, bladder, and liver. Increases in death rates were recorded for cancer of the lungs and other respiratory areas.

Project in Weight Reduction.—Persuading the 25 million adult Americans who are overweight to lose their excess poundage through intelligent dieting under medical supervision has been made a major public health project by the Metropolitan Life Insurance Company. The purpose is to effect an improvement in general health by reducing the incidence of disorders most prevalent among overweight persons. Approval and active support of the nation-wide effort is being given by the American Heart Association, the American Diabetes Association, and the American Dietetic Association. One medium by which the campaign will be carried to the public is an eight-minute animated motion picture film for theater use entitled "Cheers for Chubby." The film will be offered without rental charge to theaters throughout the country. A key activity of the campaign will be the distribution of a booklet, "Overweight and Underweight." Copies of the free booklet will be available to the public at each of the offices of the Metropolitan.

Research Foundation Director Appointed.—The Research Foundation, Chicago, a private, non-profit organization formed to produce and distribute in this country the vaccine BCG, has appointed Mr. Philip G. Rettig, Chicago attorney, as executive director. Mr. Rettig has resigned as director of research and legislation for the National Society for Crippled Children and Adults to accept the new appointment. Under his direction the foundation will continue research for greater perfection of the vaccine, expand distribution, and pursue an intensified educational program. About 60 million persons throughout the world have been innoculated with the vaccine, it is reported. At present 136 institutions in this country are using it. Continuing basic research toward improvement of the vaccine is being carried on by the University of Illinois. Gaylord Donnelley, Chicago industrialist, is president of the foundation at 26 E. Huron St., which is licensed by the National Institutes of Health as the distributor of the vaccine.

Society Elections.—At the annual meeting of the American Dermatological Association in Hot Springs, Va., Dr. Edward A. Oliver, Chicago, was elected president; Dr. Fred M. Jacobs, Pittsburgh, vice president, and Dr. Louis Brunsting, Rochester, Minn., secretary.——Dr. Thomas L. Tolan, Milwaukee, was elected president of the American Hearing Society, Washington, D. C., by its board of directors in Chicago, July 1. He is the 13th person to head the society, which was founded in 1919 by the late Dr. Wendell C. Phillips. He succeeds Dr. C. Stewart Nash, Rochester, N. Y., who has served since November, 1944. ——Newly elected officers serving during 1951 for the Society for Pediatric Research include Dr. Horace L. Hodes, New York, president; Dr. F. Howell Wright, Chicago, vice president, and Dr. Sydney S. Gellis, Boston, secretary-treasurer.——Officers for the coming year for the Association of Surgeons of the Southern Railway System include Dr. Edward T. Newell Jr., Chattanooga, Tenn., president, and Dr. J. Marsh Frere Sr., Chattanooga, recording secretary.

American Board of Obstetrics and Gynecology.—The annual meeting of the American Board of Obstetrics and Gynecology was held in New York May 10-16, at which time 248 candidates were certified, including two single certifications in gynecology. Changes made at the meeting include adoption of the following:

1. Effective Jan. 1, 1952, case reports from one's residency service shall not be more than five (5) in number.
2. Exchange residencies into other specialties cannot be permitted to subtract from the minimal requirement of three (3) years of training divided between obstetrics and gynecology.
3. Application for re-examination in Part II must be made by the candidate prior to Feb. 1 of any year.
4. A blank logbook entitled "Medical Officer's Professional Training Record" is obtainable from the office of the surgeon general. This record should be carefully kept and attested while in military service. The next scheduled examination (Part I), consisting of a written examination and review of case histories, for all candidates will be held in various cities of the United States and Canada on Feb. 1, 1952. Application for examination or re-examination must be made by the candidate prior to Nov. 1, 1951.

Dr. Paul Titus, 1015 Highland Building, Pittsburgh 6, was secretary of the board until his death on June 28.

American Leprosy Missions.—Sixty Protestant mission boards, operating through American Leprosy Missions, Inc., of 156 Fifth Ave., New York, will spend $535,917 this year on 148 colonies in 31 countries. The field covered by the missions takes in about 50,000 patients. Budgeting calls for the expenditure of $350,000 on food, clothing, and daily needs of resident patients plus salaries for doctors and superintendents; $170,000 for new hospitals, churches, schools, and homes, and $30,000 for drugs and medicines. The fund is to include $40,000 for three new colonies, one in the Belgian Congo and one in the Tanganyika region (both in Africa), and one in the Barrio Grande of Paraguay; $85,177 for 29 stations in India, and $33,400 for the Chiengmai colony in Thailand, the largest single unit. An emergency grant of $25,000 for China will be held in reserve "until political conditions permit the resumption of work in the colonies there." Asia as a whole will receive this year the benefit of $204,655, and Africa will receive $163,458. Other allocations cover $50,295 for South America, $5,828 for Europe, and $5,446 for North America. The American Leprosy Missions reported that only 2 or 3% of the estimated 10 million leprosy victims are receiving treatment in government or mission colonies.

Prevalence of Poliomyelitis.—The National Office of Vital Statistics reports that for the week ending July 7 a total of 407 cases of poliomyelitis was reported, which represents an increase of 19% over the previous week's figure of 341. For the same week last year, 478 cases were reported. The cumulative total since the seasonal low week is 2,026, as compared with 2,525 for the same period last year. No section of the country showed a marked increase in cases for the week as compared with the previous week.

Up to and including the week ended June 30, the incidence in Texas has been highest in Nueces and San Patricio counties, or about 30% of the cases reported in the state. Nearly half of the cases during this period occurred in Bexar, Harris, and Tarrant counties, all with large urban populations. In California there has been no great concentration of cases. In Louisiana 12 of the state's 30 cases during the week occurred in Shreveport. Prior to the first week of July, about one third of the cases were in the five counties in the extreme northwest part. In Oklahoma poliomyelitis cases were concentrated in Oklahoma and Garvin counties, and in Alabama nearly half the cases have been in Jefferson county.

States reporting more than 10 cases in the last two weeks are as follows:

	July 7, 1951	July 8, 1952		July 7, 1951	July 8, 1952
New York	17	29	Florida	10	8
New Jersey	5	16	Alabama	22	20
Illinois	16	19	Mississippi	17	8
Michigan	21	8	Tennessee	4	13
Wisconsin	12	6	Arkansas	15	13
Iowa	..	12	Louisiana	30	6
Nebraska	7	13	Oklahoma	21	26
Virginia	2	22	Texas	58	105
South Carolina	3	31	Colorado	21	..
Georgia	14	9	California	39	34

MEETINGS

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 6-8. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American Congress of Physical Medicine, Shirley-Savoy Hotel, Denver, Sept. 4-8. Dr. Walter J. Zeiter, 2020 E. 93d St., Cleveland 6, Executive Director.

Montana Medical Association, Great Falls, Sept. 13-16. Mr. L. R. Hegland, 104 N. Broadway, Billings, Executive Secretary.

National Medical Association, Philadelphia, Aug. 20-24. Dr. John T. Givens, 1108 Church Street, Norfolk 10, Va., General Secretary.

Nevada State Medical Association, Riverside Hotel, Reno, Sept. 13-15. Dr. Wesley W. Hall, 307 W. Sixth St., Reno, Secretary.

Post Graduate Medical Assembly of South Texas, Shamrock Hotel, Houston, Texas, July 23-25. Mrs. W. H. Dahme, 229 Medical Arts Bldg., Houston, Executive Secretary.

Reno Surgical Society Conference, Riverside Hotel, Reno, Nev., Aug. 23-25. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nev., Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 9-11. Dr. Maurice D. Frazer, 1037 Stuart Building, Lincoln, Nebr., Secretary.

U. S. Chapter, International College of Surgeons, Palmer House, Chicago, Sept. 10-14. Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago, Executive Secretary.

Utah State Medical Association, Salt Lake City, Sept. 13-15. Dr. T. C. Weggeland, 42 S. Fifth East St., Salt Lake City, Secretary.

Washington State Medical Association, Seattle, Sept. 9-12. Dr. James W. Haviland, 338 White-Henry-Stuart Bldg., Seattle, Secretary.

INTERNATIONAL

Association Internationale de Psychotechnique, Gothenburg, Sweden, July 24-28. Dr. Franziska Baumgarten-Tramer, Thunstrasse 35, Berne, Switzerland.

European Congress on Rheumatism, Barcelona, Spain, Sept. 24-27. Dr. Gunnar Edströn, Sweden, Secretary.

General Practitioners Study Club International, Rome, Italy, Sept. 12-15. Dr. John O'Connell, 10300 Lackland Road, St. Louis 14, Mo., U. S. A., President.

International Anesthesia Research Society, London, England, Sept. 3-7. Mr. R. W. Cope, University College Hospital, London W.C.1, England.

International Association of Allergists, Zurich, Switzerland, Sept. 23-29. Prof. A. S. Grumbach, Hygiene Institut der Universitaet Zurich, Gloriastr. 32, Zurich, Switzerland.

International Congress of Anesthesiology, Nursing School of the Salpiettre, 47 Boul de l'Hospital, Paris, France, Sept 20-22. 12 rue de Seine, Paris 6ᵉ, France, Secretariat.

International Congress on Entomology, Amsterdam, Holland, Aug. 17-24. Dr. J. de Wilde, 136 Rapenburgerstraat, Amsterdam, Secretary.

International Congress on Industrial Medicine, Instituto Superior Técnico, Lisbon, Portugal, Sept. 9-15. Dr. Luis Guerreiro, Instituto Nacional do Trabalho e Previdência, Praça do Comercio, Lisbon, Secretary General.

International Congress on Mental Health, Mexico City, Mexico, Dec. 11-19. Mrs. Grace E. O'Neill, Division of World Affairs, National Association on Mental Health, 1790 Broadway, New York 19, N. Y.

International Congress of Physical Medicine, London, England, July 14-19. Dr. A. C. Boyle, 45, Lincoln's Inn Fields, London, W.C.2, England, Honorary Secretary.

International Gerontological Congress, Hotel Jefferson, St. Louis, Mo., U. S. A., Sept. 9-14. Dr. John E. Kirk, 5600 Arsenal Street, St. Louis 9, Mo., Chairman, Program Committee.

International Poliomyelitis Congress, Copenhagen, Denmark, Sept. 3-7. Prof. Dr. Niels Bohr, Statens Seruminstitut, 80 Amager Blvd., Copenhagen S., Denmark, President.

International Society of Surgery, Paris, France, Sept. 24-29. Dr. L. Dejardin, 141, rue Belliard, Brussels, Belgium, Secretary General.

International Society for the Welfare of Cripples, Fifth World Congress, Stockholm, Sweden, Sept. 9-14. Mr. Donald V. Wilson, 54 E. 64th St., New York 21, N. Y., U. S. A., Executive Director.

Pan Pacific Surgical Association Congress, Honolulu, Hawaii, Nov. 7-19. Dr. Forrest J. Pinkerton, Suite 7, Young Bldg., Honolulu, Hawaii, President.

Students' International Clinical Congress, Leyden, Utrecht, Groningen and Amsterdam, Holland, July 10-28. N. A. M. Bergstein, Oude Gracht 143 bis, Utrecht, Holland, Secretary General.

World Confederation for Physicial Therapy, Copenhagen, Denmark, Sept. 7-8.

World Medical Association, Stockholm, Sweden, Sept. 15-21. Dr. Louis H. Bauer, 2 E. 103d St., New York 29, N. Y., U. S. A., Secretary-General.

EXAMINATIONS AND LICENSURE

BOARDS OF MEDICAL EXAMINERS

Arizona:* *Examination.* Phoenix, July 17-19. *Reciprocity.* Phoenix, July 21. Sec., Dr. J. H. Patterson, 316 W. McDowell Road, Phoenix.

California: *Written.* San Francisco, Aug. 20-23. *Oral.* Los Angeles, August 18. *Oral and Clinical Examination for Foreign Medical School Graduates.* Los Angeles, August 19. Sec., Dr. Frederick N. Scatena, 1020 N St., Sacramento 14.

Colorado:* *Reciprocity.* Denver, July 10. Sec., Dr. George H. Gillen, 831 Republic Bldg., Denver 2.

Connecticut:* *Regular. Examination.* Hartford, July 10-11. Sec to the Board, Dr. Creighton Barker, 160 St. Ronan St., Hartford. *Homeopathic.* Derby, July 11-12. Sec., Dr. Donald A. Davis, 38 Elizabeth St., Derby.

Delaware: *Examination.* Dover, July 10-12. *Reciprocity.* Dover, July 19. Sec., Dr. J. S. McDaniel, 229 S. State St., Dover.

Georgia: Atlanta, June, August, Oct. 9-11. Sec., Mr. R. C. Coleman, 111 State Capitol, Atlanta.

Guam: The Commission on Licensure will meet whenever a candidate appears or submits his credentials. Ex. Sec., Dr. John Y. Battenfield, Agana.

Hawaii: *Examination.* Honolulu, July 9-12. Sec., Dr. I. L. Tilden, 1020 Kapiolani St., Honolulu.

Idaho: Boise, July 9-11. Sec., Mr. Armand L. Bird, 305 Sun Bldg., Boise.

Maine: Augusta, July 10-11. Sec., Dr. Adam P. Leighton, 192 State St., Portland.

Massachusetts: *Examination.* Boston, July 10-13. Sec., Dr. Robert C. Cochrane, Room 37, State House, Boston 33.

Nevada:* Carson City, August 6. Sec., Dr. G. H. Ross, 112 North Curry St., Carson City.

New Hampshire: Concord, Sept. 12-13. Sec., Dr. John Samuel Wheeler, Room 107 State House, Concord.

New Mexico:* Santa Fe, Oct. 8-9. Sec., Dr. Charles J. McGoey, Coronado Bldg., Santa Fe.

North Carolina: *Reciprocity.* Morehead City, July 28. Sec., Dr. Joseph J. Combs, 419 Professional Bldg., Raleigh.

North Dakota: Grand Forks, July 4-7. Sec., Dr. C. J. Glaspel, Grafton.

Ohio: *Examination.* Columbus, December. *Reciprocity.* Columbus, Aug. 14 and Oct. 2. Sec., H. M. Platter, 21 W. Broad St., Columbus 15.

Oregon:* *Examination.* Portland, July 5-7. Sec., Mr. Howard I. Bobbitt, 609 Failing Bldg., Portland 4.

Pennsylvania: *Examination.* Philadelphia and Pittsburgh, July 10-13. *Acting Sec., Mrs. M. G. Steiner, 351 Education Bldg., Harrisburg.*

Puerto Rico: *Examination.* Santurce, Sept. 4. Sec., Mr. Luis Cueto Coll, Box 3717, Santurce.

Rhode Island:* *Examination.* Providence, July 5-6. Administrator of Professional Regulation, Mr. Thomas B. Casey, 366 State Office Bldg., *Providence.*

South Dakota: Rapid City, July 17-18. Sec., Dr Clarence E. Sherwood, 109 Center St., West, Madison.

Texas:* *Reciprocity.* Marlin, Aug. 5. Sec., Dr. M. H. Crabb, 1714 Medical Arts Bldg., Ft. Worth.

Utah: Salt Lake City, July 11-13. Asst. Dir., Mr. Frank E. Lees, 324 State Capitol Bldg., Salt Lake City 1.

Washington:* Seattle, July 16-18 Sec., Department of Licenses, Mr. Edward C. Dohm, Olympia.

West Virginia: Charleston, July 9-11. Sec., Dr N H. Dyer, Capitol Bldg., Charleston 5.

Wisconsin:* Milwaukee, *July 10-12.* Sec., Dr. C. A. Dawson, River Falls.

BOARDS OF EXAMINERS IN THE BASIC SCIENCES

Alaska: Juneau, August. Sec., Dr. C. Earl Albrecht, Box 1931, Juneau.

District of Columbia: *Examination.* Washington, Oct. 22-23. Sec., Dr. Daniel L. Seckinger, 4130 E. Municipal Bldg., Washington.

Iowa: *Examination.* Des Moines, July 10. Sec., Dr. Ben H. Peterson, Coe College, Cedar Rapids.

Michigan: Detroit and Ann Arbor, Oct. 12-13. *Examination.* Sec., Miss Eloise LeBeau, 501 W. Michigan Ave., Lansing 15.

Minnesota: *Examination.* Minneapolis, Oct. 2-3. Sec., Dr. Raymond N. Bieter, 105 Millard Hall, University of Minnesota, Minneapolis.

Nebraska: *Examination.* Omaha, Oct. 2-3. Director, Bureau of Examining Boards, Mr. Oscar F. Humble, Room 1009, State Capitol Bldg., Lincoln 9.

Nevada: *Examination.* Reno, July 3. Sec., Mr. Frank Richardson, University of Nevada, Reno.

Oklahoma: Oklahoma City, Sept. 14. Sec., Dr. Frank C. Gallaher, 813 Braniff Bldg., Portland 4.

Oregon: *Examination.* Portland, Sept. 8 and Dec. 1. Sec., Dr. Charles D. Byrne, State Board of Higher Education, University of Oregon, Eugene.

Rhode Island: *Examination.* Providence, August 8. Administrator of Professional Regulation, Mr. Thomas B. *Casey, 366 State Office* Bldg., Providence.

Tennessee: *Examination.* Memphis, July 5-6. Sec., Dr. O. W. Hyman, 874 Union Ave., Memphis.

Texas: *Examination.* Austin, October. Chief Clerk, Mr. B. H. Kirk, 306 Nalle Bldg., Austin.

Washington: *Examination.* Seattle, July 11-12. Sec., Department of Licenses, Mr. Edward C. Dohm, Olympia.

Wisconsin: *Examination.* Madison, Sept. 22. Sec., Mr. W. H. Barber, Ripon College, Ripon.

---

* Basic Science Certificate required.

DEATHS

Lull, Clifford Bell ⊕ Philadelphia; born in Scranton, Pa., Feb. 3, 1894; Jefferson Medical College of Philadelphia, 1915; clinical professor of obstetrics at his alma mater from 1941 to 1946; past president of the Philadelphia Obstetrical Society; fellow of the American College of Surgeons, International College of Surgeons, American Association of Obstetricians, Gynecologists and Abominal Surgeons and the Philadelphia College of Physicians; an associate examiner of the American Board of Obstetrics and Gynecology; chief of staff and director, division of obstetrics and gynecology, Philadelphia Lying-In Hospital; consulting gynecologist and obstetrician, Philadelphia General Hospital; author of "Management in Obstetric Complications" and co-author with Dr. Robert A. Hingson of "Control of Pain in Childbirth"; editor of "Clinical Obstetrics," now in the process of publication; a member of the editorial board of *Digest of Treatment;* died in Pennsylvania Hospital July 6, aged 57.

Decherd, George Michael Jr., ⊕ Austin, Texas; born in Austin, Texas, Dec. 19, 1906; University of Minnesota Medical School, Minneapolis, 1930; professor of internal medicine at the University of Texas Medical Branch in Galveston and director of the student health service at the University of Texas, Austin; at one time on the faculty of Tulane University of Louisiana School of Medicine in New Orleans; specialist certified by the American Board of Internal Medicine; member of the American Heart Association, Central Society of Clinical Research, Society of Experimental Biology in Medicine, American Public Health Association, and the American Society of Clinical Investigation; fellow of the American College of Physicians; chief of staff, Brackenridge Hospital; visiting physician, St. David's and Seton hospitals; died March 5, aged 44, of chronic lymphatic leukemia.

Cotton, Albertus ⊕ Baltimore; born in Marysville, Kan., Sept. 23, 1872; College of Physicians and Surgeons, Baltimore, 1896; professor emeritus of orthopedic surgery and roentgenology at the University of Maryland School of Medicine and College of Physicians and Surgeons; an Associate Fellow of the American Medical Association; specialist certified by the American Board of Orthopaedic Surgery and the American Board of Radiology; fellow of the American College of Surgeons; member of the American Roentgen Ray Society and the American College of Radiology; chief, orthopedic service, Mercy Hospital; attending orthopedic surgeon, James Lawrence Kernan Hospital and Industrial School for Crippled Children; affiliated with University, Presbyterian Eye, Ear and Throat, and Sydenham hospitals; died in Mercy Hospital May 3, aged 78, of nephrosclerosis with uremia.

Martin, Edward Gillette ⊕ Detroit; born Dec. 27, 1880; Detroit College of Medicine, 1904; emeritus professor of proctology at his alma mater, now known as the Wayne University College of Medicine; specialist certified by the American Board of Surgery and the American Board of Proctology, of which he had been one of the founders; member of the American Proctologic Society; fellow of the International College of Surgeons and the American College of Surgeons; served as president of the Wayne County Medical Society; proctologist, St. Mary's Hospital and Detroit Tuberculosis Sanatorium; consulting proctologist, Receiving, Harper, Grace, and Florence Crittenton hospitals in Detroit and the Highland Park General Hospital in Highland Park; an early editor of the *Detroit Medical News*; died in Harper Hospital May 11, aged 70, of coronary thrombosis.

Sutherland, Charles Goldie ⊕ Rochester, Minn.; born in Hamilton, Ont., Canada, June 19, 1877; University of Toronto Faculty of Medicine, Toronto, Canada, 1907; during World War I was an acting major in the Royal Army Medical Corps; entered the Mayo Clinic as first assistant in roentgenology in October 1918 and was appointed consultant in the section of roentgenology in July, 1923; assistant professor of radiology at the Mayo Foundation, serving until July 1942, when he became a member of the emeritus staff; an Associate Fellow of the American Medical Association; member of the American College of Radiology and the Minnesota Radiological Society; an honorary member of the Canadian Radiological Society; specialist certified by the American Board of Radiology; died in Colonial Hospital May 4, aged 73.

Burnap, Willard Lathrop ⊕ Fergus Falls, Minn.; born in Dover, N. H., Jan. 28, 1874; Rush Medical College, Chicago, 1901; past president of the Minnesota State Medical Association and councilor of the Eighth District; in 1944 awarded the distinguished service medal of the state association for his "professional accomplishments and for service to the profession in Minnesota"; member of the Radiological Society of North America; fellow of the American College of Surgeons; member of the House of Delegates of the American Medical Association in 1926, 1927, 1928, and 1950; instrumental in the creation of the Northern Minnesota Medical Association in 1920, serving as its secretary, general manager, and president; affiliated with Wright Memorial Hospital; died May 9, aged 77, of brain tumor.

Haygood, Charles Wendell, Shawnee, Okla.; born in Hanley, Texas, Oct. 17, 1909; University of Oklahoma School of Medicine, Oklahoma City, 1935; member of the American Medical Association; passed assistant surgeon of the U. S. Public Health Service Reserve from 1942 to 1946; on the staff of the city health department of Oklahoma City; served in the Oklahoma State Health Department; came to Shawnee as director of the City-County Health Unit and served from 1940 to 1946; partner in the Keen-Haygood Clinic; on the staff of the City Hospital; business manager of the *Bulletin of the Pottawattomie County Medical Society;* died in St. Anthony's Hospital, Oklahoma City, May 8, aged 41, of hypernephroma.

Johnson, William Joshua, San Antonio, Texas; born in Cookville, Texas, Feb. 9, 1883; Fort Worth School of Medicine, Medical Department of Texas Christian University, 1907; member of the American Medical Association; fellow of the American Psychiatric Association; specialist certified by the American Board of Psychiatry and Neurology; served on the staff of the North Texas State Hospital, Terrell; at one time superintendent of the East Texas State Hospital for Insane in Rusk and the State Hospital for Senile Insane in Austin; for many years superintendent of the San Antonio State Hospital; died in Nix Memorial Hospital March 6, aged 68, of gastric hemorrhage and peptic ulcer.

Rafferty, Theodore Newell, Sebring, Fla.; born in Robinson, Ill., April 21, 1908; University of Illinois College of Medicine, Chicago, 1933; fellow of the American College of Physicians; member of the American College of Chest Physicians, National Tuberculosis Association, and the American Trudeau Society; served on the staffs of Maybury Sanatorium, Northville, Mich., Veterans Administration Hospital, New Orleans, and the Eastern North Carolina Tuberculosis Sanatorium' in Wilson, N. C.; author of "Artificial Pneumothorax in Pulmonary Tuberculosis"; died in the Ochsner Foundation Hospital, New Orleans, April 8, aged 43, of subacute bacterial endocarditis.

Freeman, Benjamin Franklin, Grosse Pointe, Mich.; born in Waco, Texas, Nov. 18, 1896; Johns Hopkins University School of Medicine, Baltimore, 1922; member of the American Medical Association; fellow of the American College of Surgeons; served a residency at the City of Detroit Receiving Hospital; chief gynecologist at Saratoga General Hospital; member of the courtesy surgical staff, Highland Park General Hospital in Highland Park, and Harper Hospital, St. Joseph's Mercy Hospital, Woman's Hospital, and Grace Hospital, all in Detroit; died May 21, aged 54, of glioblastoma.

⊕ Indicates Fellow of the American Medical Association.

Abbott, Charles E., Minden, Neb.; Western University Faculty of Medicine, London, Ont., Canada, 1902; member of the American Medical Association, died April 30, aged 74, of coronary thrombosis.

Allen, Martin Sylvester, Elizabethtown, Ky.; Kentucky School of Medicine, Louisville, 1885; formerly health officer of Hardin County; died April 17, aged 90, of pulmonary hemorrhage, arteriosclerosis, and hypertrophy of the prostate.

Armstrong, Edward Cornelius, Sussex, N. J.; University of the City of New York Medical Department, New York, 1889; died May 2, aged 87, of arteriosclerosis.

Baron, Samuel Lincoln, Philadelphia; Temple University School of Medicine, Philadelphia, 1910; an examining physician for the Army during World War I; on the staffs of Jewish and Mount Sinai hospitals; died May 3, aged 65, of myocarditis.

Baumeister, Charles F., Avoca, Iowa; Marion-Sims College of Medicine, St. Louis, 1897; past president of Pottawattomie County Medical Society; on the staff of Jennie Edmundson Hospital in Council Bluffs for many years; member of the American Medical Association; died in Bishop Clarkson Hospital, Omaha, Neb., May 4, aged 78, of carcinoma of the lung.

Bloemendaal, Edwin Gerald John, Lake Park, Minn.; State University of Iowa College of Medicine, Iowa City, 1936; member of the American Medical Association; died in St. Mary's Hospital, Detroit Lakes, April 1, aged 40, of subarachnoid hemorrhage.

Bowman, Fred Arnold ⊕ Leon, Iowa; University of Louisville (Ky.) Medical Department, 1894; Keokuk Medical College, 1898; served as coroner of Decatur County, affiliated with Decatur County Hospital; died April 12, aged 79, of carcinoma of the prostate.

Boyce, Samuel George, Little Rock, Ark.; Western Eclectic College of Medicine and Surgery, Kansas City, Kan., 1909; served during World War I; died May 3, aged 63, of prostatic hypertrophy.

Bradley, John Martin ⊕ St. Louis; Washington University School of Medicine, St. Louis, 1901; an Associate Fellow of the American Medical Association; died in De Paul Hospital May 3, aged 78, of cerebral hemorrhage.

Brigham, Jeanette M., Pasadena, Calif.; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1900; died in May, aged 76.

Britton, Roland L., Mays Landing, N. J.; College of Physicians and Surgeons, Baltimore, 1907; died March 1, aged 64, of coronary occlusion.

Bubna, Louis Edward, Cleveland; University of Rochester School of Medicine and Dentistry, Rochester, N. Y., 1932; served during World War II; on the staff of St. Alexis Hospital; physician for the Baltimore & Ohio Railroad; died May 2, aged 44, of a skull fracture received in a fall.

Buckman, Isaac, Doylestown, Pa.; Baltimore University School of Medicine, 1903; owner of a private hospital; died April 27, aged 74, of cerebral hemorrhage.

Burke, William Augustus, Brooklyn; Long Island College Hospital, Brooklyn, 1918; affiliated with Kings County, St. Peter's, and Holy Family hospitals; died May 9, aged 61.

Callerstrom, Gottfried William, Minneapolis; University of Minnesota College of Medicine and Surgery, Minneapolis, 1906; member of the American Medical Association; formerly deputy county coroner; on the staff of the Swedish Hospital; died May 6, aged 69, of coronary occlusion.

Copenhaver, Meek Marion ⊕ Knoxville, Tenn.; Tennessee Medical College, Knoxville, 1902; served during World War I; died May 3, aged 73, of coronary occlusion.

Cracroft, Thomas Byron, Asheville, N. C.; Medical Department of Tulane University of Louisiana, New Orleans, 1907; for many years affiliated with the Veterans Administration; died in Swannanoa May 5, aged 80, of lobar pneumonia.

Cutler, Franklin Earl, Wecoma Beach, Ore.; Cleveland Homeopathic Medical College, 1905; Jefferson Medical College of Philadelphia, 1906; specialist certified by the American Board of Otolaryngology; member of the American Academy of Ophthalmology and Otolaryngology and the American Laryngological, Rhinological and Otological Society; fellow of the American College of Surgeons; died in the Good Samaritan Hospital, Portland, Ore., March 30, aged 72, of cerebral hemorrhage.

Ford, William, Williamsport, Pa.; Jefferson Medical College of Philadelphia, 1914; for many years medical examiner for the Pennsylvania Railroad; died April 25, aged 65, of coronary occlusion and diabetes mellitus.

Gardner, Russell Wilson ⊕ Troy, Ohio; Ohio State University College of Medicine, Columbus, 1927; member of the American Society of Anesthesiologists; affiliated with Stouder Memorial Hospital; killed May 7, aged 53, in an automobile accident near Casper, Wyo.

Glenn, Robert Baltzell, Jacksonville, Fla.; University of Georgia School of Medicine, Augusta, 1941; member of the American Medical Association; served during World War II; died at sea, off Key West, April 25, aged 33, in an airplane accident.

Harned, John Wisdom, Hopkinsville, Ky.; University of Louisville Medical Department, 1897; member of the American Medical Association; on the staff of the Jennie Stuart Memorial Hospital; served on the local Selective Service Board during World War I and was reappointed during World War II; died April 22, aged 75, of dissecting aneurysm.

Henry, Frank Charles Jr. ⊕ Perth Amboy, N. J.; Cornell University Medical College, New York, 1921; fellow of the American College of Surgeons; director of surgery, Perth Amboy General Hospital; assistant surgeon, Roosevelt Hospital, Metuchen; consulting surgeon, New Jersey State Hospital, Marlboro, and South Amboy Memorial Hospital, South Amboy; died March 7, aged 54, as the result of an automobile accident.

Hilliard, Hercules C., Paducah, Ky.; Eclectic Medical Institute, Cincinnati, 1900; died March 15, aged 75.

Hunter, Edwin William, Greenwood, Miss.; Medical Department of Tulane University of Louisiana, New Orleans, 1901; died May 7, aged 81, of heart disease.

Irwin, Thaddeus Stevens, St. Petersburg, Fla.; Jefferson Medical College of Philadelphia, 1887; member of the American Medical Association and the Medical Society of the State of Pennsylvania; died April 12, aged 86, of arteriosclerosis.

Jorgenson, Milton Cyril ⊕ Watertown, S. D.; Northwestern University Medical School, Chicago, 1930; died April 5, aged 46, of lymphosarcoma.

Kloepper, Victor Ferdinand ⊕ St. Louis; Washington University School of Medicine, St. Louis, 1926; served during World War II; affiliated with Lutheran Hospital; died May 3, aged 50, of carcinoma of the pancreas.

Lander, William Tertius, Williamston, S. C.; Medical College of the State of South Carolina, Charleston, 1910; member of the American Medical Association and the American Trudeau Society; died May 15, aged 90, of heart disease.

Lawson, John Mack, Fort Worth, Texas; Baylor University College of Medicine, Dallas, 1934; member of the American Medical Association; fellow of the American College of Surgeons; on the staff of the Harris Memorial Methodist Hospital; died April 26, aged 41, of heart disease.

McAnerny, John Henry ⊕ Parsons, Tenn.; University of Tennessee College of Medicine, Memphis, 1933; died May 4, aged 44.

Macbeth, Harry Francis, Seattle; Milwaukee Medical College, 1904; died May 3, aged 68, of cerebral hemorrhage and cerebral arteriosclerosis.

McNabb, John Wilson ⊕ Louisa, Ky.; Medical College of Virginia, Richmond, 1923; served as president of the Lawrence County Medical Society; for many years president of the county board of health; died February 13, aged 55.

Martin, Robert Michael ⊕ Detroit; University of Michigan Department of Medicine and Surgery, Ann Arbor, 1910; affiliated with Grace, Michigan Mutual, and Children's hospitals; died in Harper Hospital April 20, aged 65, of carcinoma of the bladder.

Murtaugh, Edward G., Burlingame, Kan.; University Medical College of Kansas City, 1898; county coroner; formerly affiliated with the Indian Service; died April 7, aged 83, of cerebral hemorrhage.

Nicholson, Richard Eugene, Brenham, Texas; Medical Department of Tulane University of Louisiana, New Orleans, 1897; member of the American Medical Association; fellow of the American College of Surgeons; veteran of the Spanish-American War; chairman of the board of directors of Farmers National Bank; affiliated with Sarah B. Milroy Memorial Hospital; died February 7, aged 76, of cerebral hemorrhage.

Nowers, Walter E., Long Beach, Calif., John A. Creighton Medical College, Omaha, 1908; member of the American Medical Association and the Nebraska State Medical Association; died in Long Beach, April 17, aged 69, of myocardial infarction.

Oberholtzer, Edward James, Williamsfield, Ill.; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1903; died in Cottage Hospital, Galesburg, May 2, aged 72, of cirrhosis of the liver and diabetes mellitus.

Ogle, Clairel Leroy ⊕ Grants Pass, Ore.; Harvard Medical School, Boston, 1923; served during World War I; fellow of the American College of Surgeons; on the staff of Josephine General Hospital; died April 27, aged 57, of a compound fracture of the skull suffered in an automobile accident.

Owen, Albert Simpson, North Edgecomb, Maine; Tufts College Medical School, Boston, 1911; served with the army on the Mexican border in 1914; awarded the Croix de Guerre by the French government for his service during World War I; at one time a member of the board of education in Framingham, Mass., and on the staff of Bath Memorial Hospital in Bath; died May 4, aged 66, of coronary heart disease.

Paul, Samuel George, Salt Lake City; University of Pennsylvania Department of Medicine, Philadelphia, 1901; member of the American Medical Association; served as city health commissioner; for many years school physician; formerly chairman of the county board of health and police surgeon; affiliated with St. Mark's Hospital; died April 20, aged 74, of tuberculosis.

Pierce, Eben Douglas, Trempealeau, Wis.; University of Oregon Medical School, Portland, 1899; died May 3, aged 76, of carcinoma of the colon.

Price, Norman Wellington, Niagara Falls, N. Y.; University of Toronto Faculty of Medicine, Toronto, Canada, 1896; member of the American Medical Association and the American Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; on the staffs of St. Mary's Hospital and Memorial Hospital, where he died April 18, aged 82, of myocardial infarction.

Quillian, Edgar Pierce, Clyattville, Ga.; St. Louis College of Physicians and Surgeons, 1899; member of the American Medical Association; died in Thomasville May 2, aged 73.

Rand, Morris ⊕ Los Angeles; Baltimore Medical College, 1911; died April 8, aged 69.

Ray, Frank Leonard ⊕ Charlotte, N. C.; Medical College of Virginia, Richmond, 1919; member of the American Medical Association; served during World War I; died April 23, aged 56, of arteriosclerotic heart disease.

Reed, Josiah Frederick, Harrisburg, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1918; past president of the Dauphin County Medical Society; fellow of the American College of Surgeons; served during World War I; died in Jackson Memorial Hospital, Miami, Fla., April 25, aged 60, of adenocarcinoma of the bladder.

Richardson, Everett Wesley, Winslow, Ind.; Indiana Medical College, School of Medicine of Purdue University, Indianapolis, 1906; died March 7, aged 73, of coronary thrombosis.

Robinson, Burton Lowry, Edna, Texas; University of Tennessee College of Medicine, Memphis, 1944; served during World War II; died in Meridian, Miss., May 4, aged 30, of cerebral hemorrhage.

Robinson, Dana E. ⊕ Medical Director, U. S. Public Health Service, retired, Los Angeles; Medical College of Ohio, Cincinnati, 1896; died May 5, aged 76, of hypertensive heart disease and arteriosclerosis.

Roth, Jesse Henry, Tucson, Ariz.; University of Illinois College of Medicine, Chicago, 1915; specialist certified by the American Board of Otolaryngology; formerly practiced in Kankakee, Ill., and was past president of the Kankakee County Medical Society; formerly practiced in Jamestown, N. D., where he was on the staffs of Jamestown and Trinity hospitals; served during World Wars I and II; died May 1, aged 62.

Scarborough, James Warren, Terrell, Texas; St. Louis College of Physicians and Surgeons, 1917; member of the American Medical Association; for many years affiliated with Terrell State Hospital; died in Brackenridge Hospital, Austin, April 21, aged 76, of cardiac failure.

Schetky, Martha G. K., Philadelphia; Woman's Medical College of Pennsylvania, Philadelphia, 1897; died May 11, aged 81.

Schlosser, Charles Louis, Syracuse, N. Y.; Syracuse University College of Medicine, 1913; for many years medical examiner for the Metropolitan Life Insurance Company; died May 1, aged 70, of arteriosclerotic heart disease.

Sears, Clarence William, Youngstown, Ohio; State University of Iowa College of Medicine, Iowa City, 1932; member of the American Medical Association; served during World War II; died April 30, aged 44, of an accidental gunshot wound.

Shimer, Floyd Aaron, Phillipsburg, N. J.; Medico-Chirurgical College of Philadelphia, 1905; also a graduate in pharmacy; a trustee of Warren Hospital, where he died April 21, aged 70, of chronic nephritis and uremia.

Sibert, Aldo Vernon, West Palm Beach, Fla.; Ohio State University College of Medicine, Columbus, 1915; died April 24, aged 58, of heart disease.

Simkins, Raymond ⊕ Bridgeton, N. J.; Jefferson Medical College of Philadelphia, 1915; an Associate Fellow of the American Medical Association; died April 24, aged 72, of coronary insufficiency and arteriosclerosis.

Smith, Festus Steely, Corbin, Ky.; Hospital College of Medicine, Louisville, 1905; member of the American Medical Association; owner of Smith Hospital; died in Fort Lauderdale, Fla., April 8, aged 71.

Stern, Hyman Bernard, Philadelphia; Medico-Chirurgical College of Philadelphia, 1908; died in Jewish Hospital April 13, aged 65, of cerebral hemorrhage.

Sweet, Austin Dryden, Martinsville, Ind.; Indiana University School of Medicine, Indianapolis, 1923; member of the American Medical Association; served during World War I; for two terms county coroner; died in the Veterans Administration Hospital, Indianapolis, April 22, aged 56.

Taussig, Joseph Bondi, St. Louis; Washington University School of Medicine, St. Louis, 1931; member of the American Medical Association; served during World War II; on the staffs of the Veterans Administration Hospital in Jefferson Barracks, Mo., and Jewish Hospital, where he died May 8, aged 46, of cerebral hemorrhage.

Willis, Benjamin Coleman ⊕ Cincinnati; University of Virginia Department of Medicine, Charlottesville, 1902; affiliated with Christ Hospital; died April 15, aged 73, of heart disease.

Wilson, Homer Smith, Saugus, Calif.; University of Michigan Homeopathic Medical School, Ann Arbor, 1908; member of the American Medical Association; died May 1, aged 68.

Woods, Samuel D. E. ⊕ Osawatomie, Kan.; Hahnemann Medical College of the Kansas City University, Kansas City, Mo., 1902; on the staff of State Hospital, where he had been superintendent for many years; died April 2, aged 73, of arteriosclerosis, diffuse pulmonary fibrosis and myocarditis.

GOVERNMENT SERVICES

DEPARTMENT OF DEFENSE

Appointments of Drs. Blake and Spencer.—Dr. Francis G. Blake, Sterling Professor of Medicine at Yale University School of Medicine, has been appointed scientific director, Medical Research and Development Board, Office of the Army Surgeon General. Dr. Blake recently resigned the chairmanship of the committee on medical sciences, Research and Development Board, Department of Defense. His new position is the most responsible civilian post in medical research in the Army. He will assist in planning and supervising the Army Medical Service research and development program, of which over 200 projects already are under way. On the Yale faculty since 1920, Dr. Blake was dean of medicine from 1940 to 1947. During World War II he served in a civilian capacity as consultant to the secretary of war and, beginning in 1941, for five years as a member of the board of investigation of epidemic diseases in the U. S. Army.

Dr. Thomas B. Spencer has been appointed executive director of the committee on medical sciences, Research and Development Board, Department of Defense, succeeding Dr. Joseph M. Pisani, who will become assistant dean and instructor in medicine of the State University Medical Center at New York City. Dr. Spencer has served as deputy executive director of the committee since Aug. 1, 1950. Prior to that he was in private practice in Rochester, N. Y., and held staff appointments at Strong Memorial Hospital, Genesee Hospital, and Rochester General Hospital. Since September, 1950, he has been an instructor in clinical medicine at George Washington University.

Dr. Albert Rives Shands Jr., surgeon-in-chief of the Alfred I. duPont Institute of Wilmington, Del., has been appointed a member of the Armed Forces Medical Policy Council succeeding Dr. W. Randolph Lovelace II, who has been appointed chairman of the Council.

VETERANS ADMINISTRATION

Physicians Wanted.—The Veterans Administration Hospital, Downey, Ill., has vacancies for several physicians in the 217-bed tuberculosis unit of the hospital, as well as for an internist in the general medical unit. Salaries for the positions are determined by the experience and qualifications of the applicant. The salary range for physicians in the department of medicine and surgery includes: junior grade, $5,000 per year; associate grade, $5,400 per year; full grade, $6,400 per year; intermediate grade, $7,600 per year; senior grade, $8,800 per year, and chief grade, $10,000 per year. An additional allowance of 25% of the base salary is given those having a rating of specialist as approved by an American specialty board. Determination of the appropriate grade for applicants will be made by thorough evaluation of qualifications by a professional standards board. Promotions are available after meeting length of service and other requirements of the Veterans Administration. In addition, physicians are granted 30 days vacation and 15 days sick leave each year. Applicants should write to the Veterans Administration Hospital, Downey, Ill. The hospital is 35 miles north of Chicago, and five miles south of Waukegan, Ill.

New Hospital Managers.—The Veterans Administration has announced the appointment of new managers for three of its hospitals. The new managers are Dr. Edward S. Post, for the hospital in Sheridan, Wyo.; Dr. George S. Littell, for the Dallas, Texas, hospital, and Dr. Morris C. Thomas, for the hospital soon to be completed in Madison, Wis. Dr. Post, formerly manager of the VA hospital in Fort Custer, Mich., has moved to Sheridan to replace Dr. Victor H. Bean, who has been transferred to the Alexandria, La., hospital. Dr. Littell replaces Dr. Frederick R. Eastland, who recently resigned. Dr. Thomas presently is manager of the Waukesha, Wis. hospital.

Appoint Two Consultants.—The Veterans Administration has announced the appointment of two physicians to fill long-time vacancies on the Board of Chief Consultants. They are Dr. Charles L. Brown of Philadelphia, head of the department of medicine at Temple University and Hahnemann Medical School, and Dr. Charles E. Kossmann, associate professor of medicine at New York University. Dr. Brown was appointed chief consultant in internal medicine, and Dr. Kossmann received his appointment for cardiology. Both men were selected from a list of specialists submitted by the Board of Chief Consultants at its recent meeting in Washington, D. C.

PUBLIC HEALTH SERVICE

Experimental Thyroid Cancers.—Harold P. Morris, biochemist at the National Cancer Institute of the Public Health Service, has been awarded the second prize in competition for the 1951 Van Meter prize awarded by the American Goiter Association. The award was made for a paper reporting that for the first time experimental cancers of the thyroid gland have been produced in animals. The cancers are transplantable to normal animals. The report is based on studies in progress at the institute for more than six years.

The first step in producing the experimental tumors is to block the secretion of the thyroid gland by adding a small amount of thiouracil to the animal's diet. The resultant thyroid deficiency causes an increase in the secretion of the hormone thyrotropin by the pituitary gland. Over-secretion of this hormone is thought to be accompanied by the under-secretion of other hormones, another unbalancing factor. Continuance of imbalance over a long period ends in malignancy. This tumor is thought to be caused by the prolonged stimulation of thyroid tissue by the thyrotropic hormone.

The discovery is a major advance in the laboratory attack on problems of thyroid cancer, according to Dr. John R. Heller, director of the National Cancer Institute. The possibility of a similarity between thyroid tumors in the mouse and those in humans, which was suggested by these experiments, has resulted in a new phase of thyroid tumor research at the National Cancer Institute. Exploratory studies in this field have found that some of the mouse thyroid tumors behave much like human thyroid tumors in that some have low ability to pick up radioactive iodine, and others show a high attraction for it. This finding makes possible studies to determine which factors influence the ability of thyroid tumors to concentrate administered radioactive iodine.

Venereal Disease Clinics.—The new Directory of Venereal Disease Clinics published by the U. S. Public Health Service carries summaries of prenatal and premarital laws, names and addresses of each diagnostic and treatment facility, and lists of laboratory facilities of each state, Marine hospitals, and facilities for American seamen.

There are 2,267 public venereal disease clinics in the United States and territories of Alaska, Hawaii, and Puerto Rico. North Carolina leads all other states, with 222 venereal disease clinics; Mississippi has 176; Georgia, 155; Pennsylvania, 139; Florida, 131; California, 118; Kentucky, 106; Texas, 101; South Carolina, 97, and Louisiana, 93. All other states have fewer than 90 clinics. These facilities were reported by the states and territories to the Public Health Service as of November, 1950.

The directory also shows that 42 states have prenatal laws requiring blood tests, and 41 states have premarital laws requiring blood tests and physical examinations for venereal disease. States not having prenatal laws are Alabama, Maryland, Minnesota, Mississippi, Tennessee, Wisconsin, and the District of Columbia. Arizona, Maryland, Minnesota, Mississippi, Nevada, New Mexico, Texas, and the District of Columbia do not have premarital laws. Alaska and Hawaii have both premarital and prenatal laws. Puerto Rico does not have either law, as such, but there is space on each "Certificado de Matrimonio" for a physician to state that applicants do not have mental disease, epilepsy, or syphilis.

FOREIGN LETTERS

LONDON

Royal Cancer Hospital Centenary.—The centenary of the Royal Cancer Hospital of London was celebrated on May 17, 1951. There was a reception at the hospital and demonstrations in the Chester Beatty Research Institute. At the centenary dinner, the chairman of the hospital board, Sir Edward Cripps, read a message from the King, congratulating the hospital on its great work during the hundred years of its existence and wishing it continued success.

Sir Henry Dale spoke of Dr. William Marsden, who founded the hospital at Hollywood Rd., West Brompton, after his wife died of cancer. It was later moved to its present site in Fulham Rd. It was the first hospital to deal solely with cancer. Sir Henry spoke of the lack of encouragement the hospital received in early days, as others did not altogether approve of a charitable hospital for one disease, but the founders persisted with their "courageous enterprise," their efforts being rewarded by a magnificent record for the hospital during the ensuing years. The speaker also thought it fit that the centenary of this hospital should fall in the Festival Year. Many scientific discoveries had been made since the 1851 exhibition; not all of them, unfortunately, had been used to further medical science, but there were many scientific advances made during the urgency of war which were subsequently adapted for human use.

Lord Horder, consulting physician to the hospital, speaking as the oldest member of the staff, recalled personalities of the past with whom he had been associated in his work. He pointed out the immense contributions to medical knowledge that had been made by special hospitals.

Mr. Oliver Lyttelton, president of the hospital, paid tribute to the work of the medical profession. He was glad that research institutions did not come under the control of the National Health Service, saying how essential it was that they should remain free of government control. With such control, there came inevitably a tendency to uniformity, followed closely by mediocrity. In no profession was uniformity more inappropriate than in medicine.

Mr. Hilary Marquand, Minister of Health, said the Royal Cancer Hospital was an institution of which the country and the commonwealth could be proud. Its change in ownership with the institution of the National Health Service brought no change in the purpose of the hospital's work. He was pleased that a film was being prepared to bring to public attention the dangers of cancer, the purpose of this film being to reassure, not to terrify, and to enable early diagnosis to be made. Cancer, he said, was the deadliest of foes and a challenge to all concerned in finding it, and the hospital could be proud of the hundred years spent in attempting to overcome the disease.

Demonstrations at the Chester Beatty Research Institute illustrated the contributions of various sciences to cancer research. In cytology, the effect of radiation and various chemicals on cell structures was shown. Methods of study of the cell by means of ultraviolet micrography and microspectography, phase-contrast micrography, cinemicrography, and electron micrography were exhibited.

There were other demonstrations, which included the preservation of chick tumor viruses by freeze-drying, electrophoretic diffusion studies, and biochemistry of tumors and of carcinogenetic and radiomimetric substances. There was also a historical section, illustrating the earlier experiments on carcinogenesis, and in the institute library many original papers were on display.

Burlington House.—It used to be the duty of one of the early members of the Royal Society to devise a new experiment each week for demonstration to the assembled fellows. Nearly three centuries have passed since then, and science has become infinitely more complicated and scientists "devilishly sophisticated." These facts are reported by the *British Medical Journal* of June 2, 1951, in an annotation about the Annual Evening Party *conversazione* held at Burlington House. The demonstration for this year consisted of about 30 exhibits conveyed in a straightforward manner and their inventors were at hand to explain their work in simple language. Several concerned the sea, one for instance showing how the deep sea floor can be bored for samples and analyzed to reveal a million years of the earth's history. Another took a series of flashlight photographs of the sea bottom at a depth of 150 ft. The annotation calls it a kind of marine census.

Other maritime exhibitions were contained in tanks, for example, hermit crabs in transparent shells, pink and greenish shrimps, long feathery worms, and a sleepy octopus. There was also a transparent, slowly turning wheel, containing sea water and many tiny shell fish. This apparatus was used for measuring swimming speeds and changes induced in them by the passage of day into night. One exhibit displayed the skulls of South African ape men, whose brows were ridged and whose massive jaws contained carious teeth. These were the skulls of men dead for a million years. There was also an impression in stone of the skin of a dinosaur. Some films were shown of snakes and the treatment of snake bite, and how spermatozoa and red cells may be kept at a temperature of 79 C. in the presence of glycerin.

This is a rare display even for London, showing as it does living animals and apparatus used on the very frontiers of research. Unfortunately, the *conversazione* was confined to fellows of the Royal Society and their guests. The *British Medical Journal* expresses regret that such demonstrations, having been shown at the Royal Society, cannot be made available to the general public and even brought to the country in the form of a traveling show. Appropriate ministerial departments, it is suggested, could well afford to finance such an undertaking. There is the continual risk that science should appear too remote and theoretical to the man in the street, but public experiments performed as they were in the day of Pepys can do much to further public knowledge of Science.

Barber-Surgeons.—In the *British Medical Journal* Supplement of June 2, 1951, Dr. A. K. P. Tobin says that the trade or profession of barber-surgeons, a flourishing one some two or three centuries ago, was put out of existence when the law forbade the practice of its more enterprising members of relieving their patients of varying quantities of blood, thus severing the connection between tonsorial and medical practitioners. The correspondent draws a present day analogy between these two forms of art. The barber, or hairdresser, charges 21 cents per head per haircut, and this operation can be repeated at a minimum of monthly intervals, thus giving the barber an annual capitation fee of $2.50 at least, as this does not include tips. The correspondent's hairdresser can average five haircuts an hour, thus controlling a panel of 1,000 clients, working 48 hours a week for a 50-week year. The family doctor, working 48 hours a week in a semirural area, cannot hope properly to look after more than 1,500 patients. The "looking after" includes night calls, unremunerated overtime and interrupted Sundays. Overhead expenses also are much heavier, and the responsibility, of course, is much greater.

The correspondent's conclusion is that, by balancing tips and quick sales, on the one hand, with maternity and special examination fees, on the other, the net incomes are similar in the two cases. He concludes with the pious hope that the Ministry of Health will not exploit too long the love of medical men and women for their calling.

Taking the Cure.—The *Lancet* of May 26, 1951, reports the findings of the British Medical Association Sponsor Committee, under the chairmanship of Lord Horder, on the place of the spa in modern practice. The report is in the form of a guide on all the spas in Great Britain, giving information with regard to the various forms of treatment at each spa. The committee is of the opinion that spa treatment can be of great value in chronic arthritis of rheumatoid and degenerative types. The rheumatism

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

that affects muscles and fasciae and the fibrositic type generally can also be relieved. Other conditions believed by the committee to benefit by spa treatment are inflammation of the urinary tract and pelvic disorders in women. The committee believes that spas could play a greater part in the convalescent treatment of both surgical and medical patients.

The committee feels that the profession tends to underestimate the value of spas and fails to appreciate the progress made at these centers in recent years. Closer cooperation among spa hospitals, universities, and teaching hospitals would promote research and insure greater continuity of treatment, standardized investigations, and follow-up. If this cooperation came about, spa treatment would then take its proper place in the National Health Service.

DENMARK

Cortisone and ACTH.—The organ of the Danish Medical Association, *Ugeskrift for Laeger,* reviews the present position in Denmark with regard to cortisone and corticotrophin (ACTH). Remarkably good results have been achieved in cases of rheumatic fever, the temperature and swelling of the joints subsiding in a day or two and symptoms referable to the heart disappearing quickly. Diseases of the eye, such as iridocyclitis and keratitis, and diseases of the skin, such as malignant pemphigus, have responded dramatically, and it has been found that the local instillation of cortisone gives satisfactory results in diseases of the eye. The supply of cortisone being very limited, its use has hitherto been largely reserved for experimental work. The situation is better with regard to corticotrophin, which since the autumn of 1949 has been available from home sources. Denmark, being a great exporter of bacon, should be able to produce large quantities of corticotrophin from the pituitary glands of pigs, and the highly developed chemical industry should ultimately succeed in producing well-standardized preparations of corticotrophin. Meanwhile the supplies of cortisone and corticotrophin now available are so small that they cannot meet the needs of even a small fraction of the patients anxious to give them a trial. The number of those who have been able to derive benefit of many months' duration under prolonged treatment is still rather small.

Index Medicus Danicus.—Up to 1912, the University Library in Copenhagen collected Danish medical publications in typewritten sheets under the heading *Bibliotheca Medica Danica.* Between 1913 and 1927 a card index was kept of Danish medical publications under the heading *Index Medicus Danicus.* After 1928, Drachmann undertook the editing of this work, which he continued for 22 years, to the end of 1949, in card index form. Now this form, accurate but rather cumbersome, has been replaced by the printed word. Four numbers of this new publication are to appear every year, and the subscription for a year is 25 Danish crowns. The *Index* groups Danish medical publications under such headings as medicine, surgery, and pediatrics, and provision is made for cross references when, for example, a fibroma of the ovary comes under the headings of both tumors and gynecology. The output of Danish medical publications is now so great and their standard so high that this *Index* is certain to prove increasingly valuable.

Effects of Tonsillectomy on Children.—A follow-up study of children undergoing tonsillectomy has recently been undertaken by Dr. Boy Kromann and Dr. Preben Eilersen at a children's hospital (Dronning Louises Börnehospital) where this operation was performed on 450 children during the five-year period 1945-1949. The indications for tonsillectomy were (1) repeated attacks of acute febrile tonsillitis, (2) chronic tonsillitis with or without signs of dyspepsia, (3) tonsillitis associated with involvement of the kidneys, heart, or joints, as well as chorea, (4) presence of mechanical interference with speech, respiration, or swallowing, and (5) presence of conditions such as colic and enuresis which might be connected with recurrent tonsillitis. Mere hypertrophy of the tonsils was not an indication for tonsillectomy. Almost all the patients belonged to the first two categories. The dyspepsia in the second category usually took the form of recurrent attacks of malodorous diarrhea associated with anorexia and a poor general condition.

The follow-up study was undertaken three to 48 months after the operation, and care was taken to make a searching examination of the patients in the hospital. Altogether 217 children were examined after an average interval of about two years. The ages of these 217 children ranged from 2 to 15 years, and all of them had suffered from recurrent infections of the throat; 44 had also suffered from the dyspeptic symptoms already referred to. It was found that the catarrhal symptoms had vanished in 71% and the dyspeptic symptoms in 75% of the children. In no case had conditions grown worse since the operation. Dr. Kromann and Dr. Eilersen find tonsillectomy to be a useful remedy for dyspeptic disturbances combined with recurrent infections of the throat in childhood.

Food Poisoning Due to Bacillus Cereus.—In 1950 a veterinary surgeon, St. Hauge of Oslo, published a preliminary account of outbreaks of food poisoning due, in his opinion, to a hitherto overlooked germ, Bacillus cereus. His observations have lately been confirmed by his Danish colleagues O. Christiansen, Svend O. Koch, and P. Madelung, who report on an outbreak of food poisoning in a summer camp near Aarhus in Denmark. The symptoms were colic, nausea, and diarrhea without fever or any severe general disturbance. An investigation led to exoneration of the water and milk supply, and the peccant article of food proved to be a yellow pudding from which Bacillus cereus was isolated in pure culture. Most of the pudding had been prepared on the day before it was eaten, and it had been kept at temperature calculated to promote the growth of this organism. Fifteen of the 18 adults and 106 of the 130 children between the ages of 8 and 16 who had eaten this pudding fell ill. Pathogenic intestinal bacteria were not found in the feces. In the Norwegian outbreaks, also, stool examinations yielded little information.

TURKEY

Urinary Schistosomiasis.—When Syria and Iraq were part of the Turkish empire, many of the inhabitants of these provinces were treated for schistosomiasis in the government and municipal hospitals. The disease is rare in the present boundaries of Turkey. Isolated cases of schistosomiasis are occasionally seen in Istanbul, Ankara, and Izmir hospitals, but the disease has invariably been contracted in Syria, Iraq, or Saudi Arabia. In August, 1950, the Ministry of Health and Social Assistance appointed parasitologist and entomologist Dr. Mahmut Sabit Akalin, director of the School of Hygiene, Dr. Kemal Alpay, director of malaria control work of the Mardin region, and Dr. V. M. Yavuz Engin, of the Refik Saydam Institute of Hygiene, to make inquiries concerning schistosomiasis in the southern provinces of Mardin and Urfa, which border on Syria and Iraq. After conferring at the border with Dr. Rushdi Tarazi, director general of hygiene for Syria, and Dr. Abdel Halim Alemi, director of health at Damascus and chief of the Bilharzia division of the Ministry of Health, the mission concentrated on the villages along the Mardin-Nusaybin border and especially on the Tel-Abiad and Kubour El Bid Syrian regions; investigation revealed that 60 to 70% of the rural population were affected. Careful examination of hundreds of persons in Turkish villages revealed that a few cases of hematuria existed there; clinical and microscopic examination revealed the presence of Schistosoma hematobium. These patients formerly lived or visited in Syria and had contracted the disease there. Many brooks and streams that have their source in Turkish territory flow into Syria. Every kind of snail found in Turkish fresh waters has been examined; Schistosoma hematobium hosts, Bulinus contortus, were not found in these waters, though a great many were found in the same waters of the Syrian territory. The Sublag and Djerrahi brooks had many other kinds of mollusks. Bifid-tailed cercariae were found in the waters of Syrian territory but not in Turkish territory. Snails from both territories were left in experimental tubes with drinking water; the Syrian tubes later exhibited Bulinus contortus and Miracidia, which were absent in the Turkish tubes.

Dr. Abdel Azim Bey, director of rural hygiene at the Ministry of Public Health, Cairo, Egypt, who on behalf of the World Health Organization as expert consultant investigated schistosomiasis in the Middle East, confirmed that 60 to 70% of the inhabitants of the Tel-Abiad and Kubour El Bid regions were infected with Schistosoma hematobium, that urinary schistosomiasis is endemic in the rural communities of southern Iraq around lake Khors and around the waters it receives, and that in northern Iraq isolated cases of schistosomiasis are encountered. Dr. Abdel Azim Bey pointed to the potential danger of the presence of fresh water snails in the rain water of swamps and streams in western Saudi Arabia in the regions of Taif, south of the holy city of Mecca. Schistosomiasis also exists among the workmen of the Saudi Arabian oil industry at the Persian gulf, where 22 of 25 school children examined were found to be infected. Investigation revealed that the disease is endemic in eastern Saudi Arabia, where the fresh waters harbor a great many snails.

Phytobezoar.—A phytobezoar was removed by Dr. Faruk Tuzener, chief at the surgical department of the Tokat government hospital. The patient was a 15 year old shepherd boy. He complained of a swollen abdomen, pain in the stomach, fainting, and epileptic fits. Six months before his admission to the hospital a doctor had administered santonin, and the patient passed 35 ascarides, which resulted in relief from pain for a month. Then the pain in the stomach, vomiting, and fainting recurred. The patient had a good appetite but was afraid to eat and lost weight. Significant findings at the time of admission were limited to the abdomen, which was greatly distended; a large, firm, mobile foreign body, with a rough surface and the size of a fist, was palpated. Generalized tenderness was present. The liver, spleen, and kidneys were in normal position. Exploratory laparotomy revealed a greatly distended stomach of normal color and maturity, with slightly thickened walls and a mobile mesogastrium. A firm, mobile foreign body in the stomach was palpated; gastrotomy was performed and a phytobezoar removed. It was oval and firm, weighed 320 gm., and consisted of a fermented mass of gray-green fiber and fruit rind.

THE PHILIPPINE ISLANDS

Physician Population.—There are about 6,900 physicians in the Philippine Islands, which has a population of 19,000,000. About one-third of the physicians reside in the capital, Manila, a city of over 1,000,000 population. The country has three schools of medicine, located in Manila; one is government owned, and the other two, including the well-known University of Santo Tomas, which was founded in 1619 by the Spaniards, are privately owned. A considerable number of the leading physicians here had their postgraduate training in universities in the United States.

Third Health Officers' Convention.—The third postwar Health Officers' Convention was held in Manila April 23-30, under the auspices of the bureau of health. The district health officers of some 53 provinces, 26 city health officers, and many physicians and dentists from all over the islands attended. The program included many refresher demonstrations in various medical activities, chiefly in the field of public health. Dr. Felipe Arenas, director of the bureau of health, and Dr. Mariano Icasiano, president of the League of District and City Health Officers, were the chief organizers. They received effective support from the secretary of health, Dr. Juan Salcedo Jr.

First South East Asia Medical Conference.—The first South East Asia Medical Conference was held simultaneously with the 44th Philippine Medical Association Convention. Dr. Abdul Kadir, delegate of Indonesia; Dr. Lim Uy Tao, from Nationalist China; Dr. Thongplensou, from Thailand; Dr. Francisco Roque, from the U. S. Public Health Service, and Dr. Carlos Ferrufino, delegate of the World Health Organization, Western Pacific Regional Office, attended this conference, which was organized by the Philippine Medical Association. Probably because of the economic and political instability in the majority of the Asiatic countries, many of them did not send delegates, therefore, this conference's achievements were limited. The Philippine delegate, explaining why this conference was called, said, among other things, "It is not safe to confine one's self solely to the medical problems of a country. . . . the medical problems now must be solved by countries of one geographical section. A sick man in Siam can be taken to Manila in a day, and a man with an infectious disease in Manila can be transferred to Djakarta in eight hours."

Thailand, the Philippines, and Indonesia were appointed members of a committee that will outline the plans for establishment of a South East Asia Medical Organization; the committee will consult the other countries and prepare for a convention at an early date. The World Health Organization delegate enthusiastically supported the establishment of such a medical organization and offered whatever facilities that W.H.O. might have for this purpose.

Forty-Fourth Annual Convention of the Philippine Medical Association.—Founded in 1903, the Philippine Medical Association had held its annual conventions regularly, except during World War II. The 44th convention was held May 1-6 at the University of Santo Tomas. Tuberculosis and malnutrition appeared to be the main public health problems of the Archipelago. Dr. Salcedo, director of the Institute of Nutrition and secretary of health, presented a sound plan for the fight against malnutrition. Dr. Rodolfo Gonzalez, the outgoing president of the Philippine Medical Association, emphasized the "vital problems facing medical education practice." In the closing General Session, Dr. Eugenio Alonso was installed as the new president.

BRAZIL

Nontuberculous Pulmonary Diseases and Incapacity to Work.—Drs. Durval Amorim, Ayrton Laroca, and Carlos Santos, of the Instituto dos Empregados em Transportes, an institution devoted to provide medical care, retirement, and pensions for the 135,000 workers of the transportation services of the state of São Paulo, published an analysis of the records of 2,000 successive medical examinations of applicants for compensation for incapacity to work, with special emphasis on nontuberculous pulmonary diseases. Of the 2,000 patients, 263 (13.16%) had diseases of the respiratory tract, distributed as follows: pulmonary tuberculosis, 156 (7.80% of the total); chronic bronchitis, 25 (1.25%); emphysema and pulmonary fibrosis, 24 (1.20%); bronchial asthma, 17 (0.85%); exudative pleuritis, 12 (0.60%); lobar pneumonia, 9 (0.45%); acute bronchitis, pneumonia, and bronchopneumonia, 7 (0.35%); pulmonary suppuration, 5 (0.25%); pulmonary blastomycosis and cancer, 2 each (0.10% each), and pneumoconiosis, bronchiectasis and spontaneous pneumothorax, 1 each (0.05% each). The incidence of tuberculosis (59.28%) is greater than that of any other disease of the respiratory apparatus. Chronic bronchitis, emphysema and pulmonary fibrosis, and bronchial asthma constitute the group known as chronic pneumopathies of nonspecific etiology. Chronic pulmonary diseases other than tuberculosis were present in 77 patients, or 3.85% of the total 2,000 cases and 29.24% of the cases of respiratory disease. Their incidence increases with the age of the persons in each group. Of 77 patients presenting nontuberculous chronic pulmonary diseases, only 21 returned to work, 19 of them within a year; most of them had asthma. Fifty-six retired or died within a year.

Turbidimetric Method for Determination of Small Amounts of DDT.—To control the results of mass house spraying with DDT by the National Malaria Service, a method was sought to measure accurately the small amounts of the insecticide remaining on the walls. The collection of specimens for analysis was done according to the process suggested by Alessandrini, i. e., scraping with a metal brush a surface of 25 sq. cm. Four colorimetric methods were tried (those of Alessandrini, Chaikin, Bayles and Payne, and Castillo and Stiff); all were rejected because of interference caused by the color pigments of the paints and by the emulsifiers used for the spraying. Kenk Kemp and Hilda A. Aguidar, of the Institute of Malariology, tried to adapt to microanalysis the Gunter-Neal turbidimetric method. The authors determined the amount of insecticide recovered from white, pink, gray, and yellow walls on which 1, 2, 3, and 4 mg. of DDT, respectively, had been sprayed; the respective amounts found were 1.00, 1.85, 2.99, and 3.90 mg. The method is easy to perform, without danger from the reagents, free of interference from the colored pigments of paints, and economical, since the alcohol utilized can be recovered by distillation.

CORRESPONDENCE

STREPTOCOCCUS ERYSIPELATIS NEEDED

To the Editor:—The Institute for Cancer Research urgently needs a virulent strain of Streptococcus erysipelatis isolated from an *untreated* case of erysipelas. It is recommended that any doctor willing to help us should obtain the organism by withdrawing the serum by hypodermic syringe from within the lesion and sow the material on an agar slant for shipment by air mail.

Stanley P. Reimann, M.D.,
Institute for Cancer Research,
Philadelphia 11.

SUICIDE FOLLOWING CORTISONE TREATMENT

To the Editor:—I have just perused the article "Suicide Following Cortisone Treatment" (*J. A. M. A.* 146:337 [May 26] 1951). Certainly it is of value to have this case history of suicide coincident to cortisone therapy recorded in The Journal for all to see and be thus alerted to such possible hazard. However, a patient in a state of acute reactive depression with manifest suicidal inclinations should not be allowed to remain in her own home and under the surveillance and care of her family. It has been recognized for many years that any patient possessed of suicidal intent will succeed therein unless placed in an institution where means to such self-destruction do not exist and where the patient can be given constant and skilled attention.

Such acute suicidal psychoses occur widely and have been occurring long before modern drug therapy was discovered. The imperative need for commitment of such patients has long been known. Yet the recurrence of such preventable suicides in our communities, despite our vaunted progress in medical science, points to the utility and wisdom of again stressing the point that the doctor should insist on the immediate commitment of any patient who exhibits the least inclination to homicide or suicide.

Albert Hulett, M.D.,
20 Hawthorne Ave., East Orange, N. J.

RESISTANCE TO PENICILLIN

To the Editor:—In two editorials in the April 21 issue of The Journal of the American Medical Association, emphasis is directed to the emergence of penicillin-resistant bacterial strains, inferentially warning the medical world that ominous clinical problems may develop. In the *Archives of Surgery*, April, 1945, in a paper on "Topical Use of Concentrated Penicillin in Surface-Active Solution," and in The Journal of March 30, 1946, in another one on "Nonoperative Treatment of Osteomyelitis with Penicillin," a technique of multiple chemotherapy was described, with the use of an antibiotic (penicillin) and a detergent (aerosol OT), in which factors involved in the development of resistant strains were detailed, with attention directed to methods of controlling this problem.

It is urged that all physicians using antibiotics return promptly to the basic principle of microbiology controlling this phenomenon of resistance. That clinically better results may follow the wisdom of such fundamental therapy is obvious, as was noted in the September 1950 issue of *Surgery, Gynecology and Obstetrics* ("Modern Treatment of Chronic Osteomyelitis with Topical Detergent Antibiotic Therapy").

The medical profession, especially in this country, must become immediately mindful of the damage that is being done when resistant bacterial strains emerge, for we are producing and probably disseminating another type of infectious disease in which antibiotics may do infinite harm to the patient and not only impede his recovery but hasten his death.

Edwin J. Grace, M.D.,
121 Fort Greene Pl., Brooklyn 17.

GENERAL PRACTICE

To the Editor:—Does the resurgence of the "general practitioner pose a threat to good surgical care? No! In a letter in, The Journal May 19, 1951, Dr. Edwin P. Lehman, director of the department of surgery at the University of Virginia, takes the opposite view of this question. There are many who would not agree with certain thoughts he has endeavored to develop, and it is only fair that these expressions be given voice.

No one interested in the revival of the "family doctor" has suggested that he be universally accorded surgical privilege. No one participating in the formulation of policy of the American Academy of General Practice has endeavored to support any person, member or nonmember, in his personal application for surgical appointment. However, we have endeavored to make it possible for the family doctor interested in surgery and desiring to improve himself in this field to have the opportunity for such advancement, to the same degree that he might anticipate it in other of the specialties. Certain principles have been put down in black and white whereby it is believed this can be assured without jeopardizing the proficiency of care that the patient may anticipate and, a step further, in setting up safeguards to insure a constant review and supervision of all surgical work done in order that laxity by any member of the staff may be discouraged and prevented.

Is there a scarcity of well-trained surgeons? We agree that surgical diagnosis is of paramount importance. We agree that preoperative and postoperative care is the most important element, other than diagnosis, in surgical care. Some workers do not possess mechanical ability and would never master a mechanical procedure. However, is surgical technique in itself so involved, so complicated, as to justify the awe in which the surgeon would be held? Is not his "one tract" approach to the treatment of disease a greater danger to the patient than a few added minutes on an operating table because of the surgeon's relatively lesser dexterity in tying a knot? Is it not true that at a recent sectional meeting of the American College of Surgeons an official of the college admitted that a medical audit of a hospital's records showed more unnecessary surgery was done by members of the board and the college than by a general practitioner enjoying surgical privilege? Is it not true that in many smaller communities general surgeons endeavored to treat conditions other than those purely surgical, and is it not true that their approach to such other disease would in all probability be much less adequate than would the general practitioner's approach to a surgical problem in which he had been found competent by his colleagues?

Dr. Lehman asked support for the program designed to increase interest in general practice and attract men to this field. Yet he, a general surgeon, would establish the limitation of the man in this field. Would he accept the general practitioner's limitations of his practice within the field of general surgery? Would he, for a minute, suggest to us in general practice that, if we accept his ideas regarding our limitations, we would then be left free and not subject to the limitations that would be imposed by the obstetrician, the pediatrician, the cardiologist, and members of other specialty groups?

General practice differs from the specialty fields primarily in the philosophy of the man engaged in it. The general practitioner is interested in the broad concept of medicine and is not concerned with the minutiae involved in the treatment of the rare or obscure case. That he will develop special interests and capabilities is understandable, but that he should decide what these will be and how they will be expressed is his right. That it is the responsibility of the medical profession, specialists and general practitioners, to evaluate honestly and without prejudice the professional work done in the community (which primarily concerns the hospital) is the real crux of the matter. It is necessary that the profession assume responsibility on the local level for the medical care rendered and find some means for controlling the practice of its members in all fields to guarantee that the work they perform will be done proficiently and that no artificial standards or barriers will be imposed. Standards and procedures suggested by the A. A. G. P. give promise of success in this endeavor if given adequate fair trial.

We want more men in general practice—Dr. Lehman agrees. Hospital association is essential if the practitioner (specialist or family physician) is to keep himself abreast of current medical progress. Therefore, all doctors in the area should enjoy hospital appointment. The degree of activity of the individual physician in treating a patient in the hospital, be it medical, surgical, or obstetric, should be determined by ability as demonstrated, and not by any artificial prerequisite of training or special society membership. The general practitioner will not be content to serve as the "scut boy" and must be allowed additional hospital privilege in any of the specialty fields in which he demonstrates ability. His continued cooperation in the hospital program, the continuation of his education, his increased service to his patient, and his over-all development as a citizen in the community is dependent on his being offered the opportunity of advancement. No specialty group should be allowed to impose its ideas and prerequisites for membership on the group determining a man's staff privilege.

The growth of specialty boards did much to improve medical standards. However, they were built by those who had served conscientious preceptorships in obtaining the proficiency that made possible the training of specialists now in these boards. That one would revert to a program of trial and error in the training of doctors is unthinkable. However, that one should discard the proved value of the preceptorship plan of training is equally unthinkable. That long periods of prerequisite "in residency" training should be required of all doctors is an impossibility and actually not desirable. The American College of Surgeons has done a memorable job in its hospital standardization program. They have provided for special recognition of the man in a specialty field but have also insured opportunity for the man who is found capable through his innate ability and through proper application in the field to practice procedures within it. They have expressed themselves as being opposed to the closed staff principle in regard to surgery, as well as in general.

The implied tragedy lies in the threat to good medical and surgical care through failure of the members of the medical profession properly to supervise the work done in the hospitals and not in making it possible for proficiency and ability to be the determining factors in a man's hospital activity. Arbitrary rules regarding fixed periods of prerequisite training should not be accepted as a guarantee in these regards in any specialty field. A man who has completed a stipulated period of residency training should be and is more readily accorded privilege when he confines himself to the particular field of his training. Let us then encourage all men in medicine, wherever their special interest, to contribute their part to the better care of the patient, better preparation of themselves for the service they render, more unselfish interest in those they serve, and more time to the effort to improve the relationships among those within this great profession. Progress is the keynote. Let us not hastily cast aside proved means to this end; we should adapt them so that they will contribute in these days of rapid advancement in the profession.

John O. Boyd Jr., M.D.,
Chairman, Commission on Hospitals,
American Academy of General Practice,
Kansas City 2, Mo.

REFERENCES TO CLOTTING IN BIBLICAL LITERATURE

To the Editor:—On page 280 of The Journal for May 19, the writer of the interesting letter on "Biblical Allusions to Clotting" says there are no references to clotting phenomena in the New Testament. He has evidently overlooked John xix. 34: "One of the soldiers with a spear pierced his side, and forthwith came there out blood and water." The Lord had been dead for almost three hours, so that the fluid which the Apostle calls "water" must have been serum. The time given would have been ample for clotting to begin and for some blood to remain unclotted.

Cyril E. Bousfield, M.D.,
Woolwich, Maine.

ADIE'S SYNDROME

To the Editor:—Kern's article on Adie's syndrome in The Journal (Jan. 27, 1951) brings to mind the words of Martin Joseph Routh: "You will find it a very good practice always to verify your references, sir!" Kern's first two references are incorrect. The page Kern quotes for Strasburger's article, 1388, does not exist in that volume. The articles of Strasburger appeared in *Neurol. Centralbl.* **21**:738 and 1052, 1902, and those of Saenger in the same journal, **21**:837 and 1137, 1902. Oddly enough, in their article, Kennedy, Wortis, Reichard, and Fair quote Strasburger's article as being on exactly the same page, 1388. Kern writes: "The association of a tonic pupil and the absence of tendon reflexes was first described independently by Saenger and Strasburger in 1902." Strasburger preceded Saenger in describing the tonic pupil, but nowhere did either author mention its association with "the absence of tendon reflexes." After tonic pupil had been described, many writers mentioned its association with "the absence of tendon reflexes" but did this only casually. This association is usually called Adie's syndrome because of his work of 1931 and 1932. Historic justice, however, demands mention of the work done six years before Adie's publication, that of the Frenchmen Weill and Reys (*Rev. d'oto-neuro-ocul.* **4**:433 [June] 1926). To be historically correct, an eponym containing a half dozen names would have to be applied to this syndrome. If an eponym is to be used, it should be Weill-Reys. But all this confusion can be avoided when a physiologic name is used: "pseudotabetic pupilotonia." To the student this would mean more than any eponym.

It is time that something be done to prevent this epidemic of eponyms in neurological textbooks and literature. "Tuberculous spondylitis" tells the student more than "Pott's disease," "generalized neurofibromatosis" more than "von Recklinghausen's disease," and "finger flexor reflex" more than "Hoffmann, Troemner, Rossner, Bechterew, etc., reflex." We need more physiology and fewer eponyms.

University of California Medical
School, San Francisco, 22.

COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

UNIVERSITY OF OTTAWA FACULTY OF MEDICINE APPROVED

At its meeting on June 8, 1951, the Council on Medical Education and Hospitals voted to extend its approval to the University of Ottawa Faculty of Medicine, Ottawa, Canada. The action of the Council was based on a survey carried out by representatives of the Council and the Association of American Medical Colleges, April 2-6, 1951.

This medical school was established in 1945. The course of instruction extends over a period of six years, the first year being devoted to premedical studies and the last to a required internship. The first students were admitted to the first year class in the fall of 1945. The first sixth year class was enrolled in the fall of 1950 and graduated in May 1951.

In accordance with long-standing policy, approval is not granted any medical school until representatives of the Council survey the school after instruction has been instituted in all years of the medical course. The Council's approval, however, applies to all students in good standing at the school at the time it was officially inspected in April, 1951.

At its meeting on June 1, 1951, the Executive Council of the Association of American Medical Colleges voted to recommend to that association at its annual meeting in October, 1951, that the University of Ottawa Faculty of Medicine be admitted to affiliate membership in that association. This is the class of membership held by other Canadian medical colleges.

Donald G. Anderson, M.D., *Secretary.*

MISCELLANY

THE UNITED STATES CHILDREN'S BUREAU

Prepared by Malcolm D. Lamborne Jr., of the A. M. A. Washington Office

The Children's Bureau is a federal agency authorized to advise parents on problems of child care and to help public and private agencies improve welfare and health services to children. The bureau's activities are particularly pertinent today because of legislative proposals that would give it authority to operate an Emergency Maternity and Infant Care (EMIC) program similar to the World War II plan, which paid for medical, nursing and hospital services for 1,454,000 maternity and infant cases of families of servicemen at a total of 125 million dollars.

The bureau's field of operations and budget have been steadily expanded. In 1912, the appropriation was $25,640 (all administrative) and the staff numbered 15. Now, the appropriation is approximately 32 million dollars, of which 95% is made up of grants to states, and the staff totals 260, including 17 physicians.

In the fiscal year ending June 30, the bureau received from Congress a total of $30,250,000 for grants of all types. Also available to states for grants were balances of $3,078,724 from previous years. The bureau's administrative budget for this year amounts to $1,500,000, including money for fact finding and reporting.

Miss Katharine F. Lenroot, bureau chief, estimates over three million pieces of literature, a great number of them bulletins for parents, were distributed in the past year. Some 26 million copies of *Infant Care*, first published in 1914 and revised seven times, have been sold or given away. It has been translated into six foreign languages, and is the Government Printing Office's all-time "best seller."

Miss Lenroot has been the bureau chief for 17 years. She reports to the Commissioner for Social Security who, in turn is responsible to the Federal Security Administrator. Miss Lenroot's office directs all bureau activities, formulates policies for the staff, cooperates with national and state commissions and organizations concerned with children and youth, and advises in planning for the White House Conferences on Children and Youth, which have been held approximately every 10 years since 1909. She is the U. S. member of the executive board of the United Nation's International Children's Emergency Fund.

ORGANIZATION

There are now six divisions operating under Miss Lenroot.

The *Division of Research* (Edward E. Schwartz, acting director) conducts research on physical, social, and emotional growth and development of children; develops standards growing out of research; conducts a clearing house for current research in child life; provides statistical service to the bureau, and prepares, in cooperation with the Division of Reports, bulletins on child care for parents. It has a staff of 46 and a budget for 1951 of $239,022.

The *Division of Reports* (Mary Taylor, director) publishes bulletins for professional and lay groups and a monthly periodical, *The Child;* designs exhibits for professional groups, and furnishes informational service to the press, magazines, radio, and other media. It has a staff of 23 and a budget of $247,826, including printing costs of bureau publications distributed free.

The *Division of Health Services* (Dr. Arthur J. Lesser, acting director) develops policies and recommendations for health services for mothers and children; administers grants to state agencies for maternal and child health services, for which $14,070,518 is available in fiscal 1951; administers grants to states for services for crippled children, for which $10,269,286 is available in the same period; provides advisory services for public and voluntary agencies on technical and administrative aspects of medical care and health services for mothers and children, and provides consultation to state agencies and private groups on pediatrics, obstetrics, orthopedics, cardiology, nursing, dentistry, hospital administration, physical therapy, medical social work, and nutrition. It has a staff of 80 and a budget of $494,058.

The *Division of Social Services* (Miss Mildred M. Arnold, director) develops policies for administration of grants and recommends standards of care of children by agencies furnishing social services to children in their own homes, in foster family homes, in institutions, and in juvenile courts, for which $8,988,920 is available for grants in fiscal 1951. It has a staff of 49 and a budget of $287,573.

The *Division of International Cooperation* (Miss Mary Larabee, acting director) cooperates with other countries in setting up and improving services for children under the Point IV (technical assistance) Program; provides consultation services to medical, nursing, nutrition, and social service agencies in other nations; develops training programs for professional people from other countries, and promotes international exchange of technical information on matters relating to child life. It has a staff of 9 and a budget of $71,700 from funds transferred by the State Department.

The *Division of Administrative Services* (Mrs. Laura E. Warren, director) plans and directs administrative activities essential to operation of the bureau; aids in drawing up budget and presenting it to Congress; maintains budgetary control over all bureau appropriations, and operates personnel and correspondence services. It has a staff of 42 and a budget of $146,298.

HISTORY

The Children's Bureau came into being April 9, 1912, with President Taft's signature on a bill sponsored by the late Senator William E. Borah and passed by the 62d Congress. The bill directed that the bureau shall "investigate and report upon all matters pertaining to the welfare of children and child life among all classes of our people, and shall especially investigate the questions of infant mortality, the birth rate, orphanages, juvenile courts, desertion, dangerous occupations, accidents and diseases of children, employment, legislation affecting children in the several states and territories."

Its formation is cited by child welfare leaders as an outgrowth of the first White House Conference on Children called in 1909 by President Theodore Roosevelt. The Bureau began in the Department of Commerce and Labor. In 1913, when separate departments were created, the bureau was made a part of the Labor Department and it remained there until its transfer, in 1946, to the Federal Security Agency. The year 1921 marked the beginning of a new emphasis and direction for the bureau. In that year, Congress passed the Federal Maternity and Infancy Act, popularly known as the Sheppard-Towner Act, which provided for grants to states (amounting then to $1,240,000) to assist in reducing maternal and infant mortality and for protecting the health of mothers and infants. Control of the program was vested in a Federal Board of Maternal and Infant Hygiene. The board was made up of the Children's Bureau chief, the Surgeon General of the Public Health Service, and the Commissioner of Education. It had authority to approve or reject state plans and to withhold federal funds from any state whose program was not operating as agreed on by the board and the state. During the life of the act, 45 states received grants. The Sheppard-Towner Act expired in 1929. The bureau for the next six years devoted itself exclusively to child research, fact finding and dissemination of information on child problems. With the passage in 1935 of the Social Security Act, the bureau returned to the field of state grants.

GRANTS

The Social Security Act provides for three Children's Bureau grant programs, which have continued in operation to the present time:

Maternal and Child Health Services.—Federal funds are distributed to state health departments, which use the money for the following purposes: salaries and training of professional

---

Another in a series of special studies toward better understanding of the operations of federal agencies.

personnel to conduct prenatal and postnatal clinics, well-child conferences, home and school visits by public health nurses, immunization services, medical and dental services for school-age children and other services. Including balances from previous years, there is available this fiscal year government funds of $14,070,518 for maternal and child health services. States must match half of the federal grants. The amount of federal money made available to each state is determined by a formula based on (1) the number of live births in the state in relation to total live births in the United States, (2) the state's financial need for help in providing services as indicated by per capita income, and (3) the number of live births in rural areas. Under this program, the bureau estimates that some 700,000 infants and preschool children attend well-child clinics annually, doctors make more than 2,300,000 examinations of school children, more than 170,000 expectant mothers attend medical conferences during pregnancy, and more than 1,500,000 children are immunized against smallpox and diphtheria.

Crippled Children Services.—Through state crippled children's agencies, federal funds help pay the cost of diagnosis and of medical, hospital, and convalescent care for children with crippling conditions. This year's funds for grants, including balances from previous years, amount to $10,269,286. In this program, too, states are required to match half of the grants. The amount of federal money a state may obtain is determined by a formula based on (1) the number of persons in the state under 21 years, (2) the state's financial need in carrying out its program as indicated by its per capita income, and (3) the number of persons under 21 in rural areas. Over 200,000 crippled children annually receive some kind of professional service, according to the bureau.

Child Welfare Services.—Through state welfare departments, federal funds help to support a wide range of social welfare services by paying a part or all of the salaries of trained child welfare workers for children who are neglected, orphaned, or delinquent. Some funds are used to pay for the actual care of children in foster homes. Federal funds including previous balances amount this year to $8,988,920. A state's share of grants is determined by the proportion of its rural youth under 18 years to the total rural child population. No fixed amount of matching funds is required for child welfare services grants, although each state must assume some of the cost. The bureau reports that more than 230,000 children annually receive services.

FEDERAL SUPERVISION

To qualify for funds in any of the three programs, state agencies must present plans which in the judgment of the bureau meet the requirements of the Social Security Act and assure a "good quality of service." State agencies are required to report their expenditures to the bureau at the end of each year.

All state plans are subject to approval or rejection by the bureau chief under power delegated by the Federal Security Administrator. This is in contrast to the Sheppard-Towner Act's tripartite board, which had final authority. Before funds are withheld, a state agency must be notified and opportunity for hearing given by the Federal Security Administrator. There is no provision for court appeal.

THE FUTURE

Dr. Edwin F. Daily, retiring chief of the Division of Health Services, who recently reviewed infant and maternity care progress of the last 15 years, reported a decrease of more than 80% in maternal mortality, a decline of almost 45% in infant mortality after the first few weeks, and an increase of almost 100% in the proportion of hospital deliveries. Just how much these gains may be attributed to the bureau's efforts and how much to progress in medical sciences cannot be accurately assessed. Miss Lenroot believes that federal officials should look toward new areas of activity. She emphasizes that, if civil defense or mobilization brings major family dislocations, then "new or expanded services for children will make a large claim on our public and private pocketbooks." One of these services might be another EMIC program.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Malpractice: Failure of Physician to Perform Caesarean Section When Requested by Patient.—The plaintiff sued for damages resulting from the alleged negligence of the defendant in postponing, contrary to her request, the performance of a Caesarean section. From a judgment in favor of the plaintiff, the defendant physician appealed to the court of civil appeals of Texas.

The plaintiff arranged for the defendant physician to attend her at the birth of her child which was expected to occur about two months later. She was then thirty-two years of age and had previously given birth to two children in another state, one in November, 1941, which lived only seven and a half hours and the other in November, 1942, which is a normal, healthy child. Plaintiff gave the defendant a complete history of her prior experiences and related many statements made to her by the doctors and nurses who attended her during the previous deliveries. She entered the Santa Rosa Hospital in San Antonio on the evening of November 12, 1947. Her labor, as in her prior experiences, was not steady or strong, and she was given "pitocin" which was intended to increase labor. She would have pains for a limited time and then quit, and she was taken to the delivery room in the hospital several times, but labor was not sufficiently strong or advanced to bring about the birth of the child. On the morning of the sixteenth, she was taken to the delivery room and placed under an anesthetic, was returned to her room until about 8:00 p. m. on the same date and was then again taken to the delivery room. The plaintiff introduced in evidence a statement which was signed by the defendant and entered in the hospital records showing what happened during the evening of November 16. That statement was as follows: "Patient was given a general anesthesia. Examination was made which showed that this baby's head was high. Forceps were considered, but it was decided that it would not be practical to apply forceps to the head as high as it was. Due to the fact that the patient had been in labor four days and the patient had adequate room it was thought best to do a version extraction. A deep ether anesthesia was given and hand placed up into the uterus. A very strong Bandl's ring was encountered, which would not relax even in extreme anesthesia. Nevertheless, an attempt was made to reverse the baby. Despite repeated attempts and despite the fact that the foot was drawn down to the head, the baby could not be diversed from a vertex position. In doing this the cord was found to be wrapped around the baby's neck. This became loosened and the cord prolapsed. This was divided between the head and the bony parts of the pelvis, which cut the baby's blood supply off. It was then decided to do a Caesarean section. Plaintiff was brought to the operating room still under anesthesia and transfusion was started."

It is definitely settled in Texas, said the court, that a patient has no cause of action against his doctor for malpractice, either in diagnosis or recognized treatment, unless he proves by a doctor of the same school of practice as the defendant (1) that the diagnosis or treatment complained of was such as to constitute negligence and (2) that it was the proximate cause of the patient's injuries. In order to prove that the defendant was guilty of actionable negligence in failing to deliver the child by Caesarean section on the morning of November 16 and in delaying such operation until the evening of the same date, it was necessary for plaintiff to show by competent admissible evidence that such failure and delay constituted a breach of the legal duty which the defendant owed to his patient of exercising ordinary skill and care in his professional efforts properly to deliver the child. Expert medical evidence was essential to such proof because the matter of determining whether to use forceps in the delivery of the child or to do a version extraction, or to do a

Caesarean section and when or under what circumstances, if at all, a reasonably skilful physician and surgeon would or should have resorted to any or all of these various alternatives, involved a practice of a highly specialized art and a learned profession with respect to which no layman could have any personal knowledge or experience on which the court might rely for guidance. Therefore, proper, expert medical evidence was a necessary element in, and an essential part of, the proof required of the plaintiff in order to show negligence and proximate cause.

The defendant, called as a witness by the plaintiff, was the only medical expert witness who testified in the case. He was interrogated fully and in detail under direct and cross-examination as to what he did in the diagnosis and treatment of the plaintiff and as to why he followed the course of procedure which he described. He did not testify to any fact or facts which in our opinion, said the court, showed or tended to show that he was guilty of negligence in failing to perform a Caesarean section sooner than he did. On the contrary, we think his testimony as a whole completely exonerated him of these charges. He testified that no doctor had the right to perform a Caesarean operation unless the facts in the case indicated that such operation was necessary and that he and his professional associates and consultants thought the plaintiff could have the baby normally until the evening of the sixteenth, when the operation was performed. The following questions and answers are typical of his testimony as a whole: "Q. During the course of your treatment of this woman did she ask you to take the child by Caesarean? A. Many times. Q. Why didn't you do it? A. Because I thought my judgment was better than hers." If in fact the defendant was using his best judgment in the diagnosis and treatment of his patient and if in good faith he was exercising that degree of skill and ability which constitutes good practice according to the standard of the medical profession in San Antonio and vicinity, said the court, then as a matter of law he was not guilty of malpractice or negligence and was not legally liable to plaintiff for damages flowing from bad results, if any, of his diagnosis or treatment.

The plaintiff testified that she wanted the child delivered by Caesarean operation and that she requested the defendant repeatedly, from November 14, to perform such operation. This testimony, said the court, must have been the basis upon which the jury made its findings of negligence. However, even though the plaintiff and her relatives wanted the operation to be performed sooner than it was, we do not think, the court concluded, that such desire on their part, irrespective of the reasons or motives which might have prompted the same, was sufficient to form the basis for a legal inference of negligence on the part of the defendant in failing to perform the operation sooner than he did. After due consideration of all the competent admissible evidence in the case, the court, therefore, concluded that such evidence was wholly insufficient to sustain the findings of the jury with respect to actionable negligence on the part of the defendant in failing to deliver the child by Caesarean birth on the morning of November 16 or in delaying the Caesarean operation until the evening of that day.

Accordingly the judgment in favor of the plaintiff was reversed and the cause was remanded to the trial court with instructions to enter judgment for the defendant physician.—*Christian v. Galutia*, 236 S.W. (2d) 177 (Texas, 1951).

Malpractice: Application of Doctrine of Res Ipsa Loquitur.—The plaintiff filed suit for damages for x-ray burns alleged to have been caused by the negligence of the defendant physician in administering treatments for papillomae. From a judgment in favor of defendant physician, the plaintiff appealed to the district court of appeal, second district, division two, California.

Prior to consulting the defendant for relief, the plaintiff was suffering from papillomae on the ball of each foot. The affliction had caused her considerable pain and had not responded to other treatments. The defendant administered x-ray therapy to her on three occasions at weekly intervals commencing Feb. 6, 1947. The relationship of physician and patient terminated about six weeks after the last treatment. At that time, according to the plaintiff, those portions of the soles to which x-rays had been applied were deep red at the center, pink in the circumference of the circle and it was all tender. In July, the area treated started to granulate. To use the words of the plaintiff, it "had the appearance of crystalized fruit," and from that time sloughing of the tissue continued and thereafter small blisters developed over the injured areas and over the dorsum of each foot. In February, 1948, the plaintiff was attended by a chiropodist who testified that the ball of each foot over a circle one inch and a quarter in diameter was denuded and that there was a colorless exudate from the area such as is seen in burns. The condition did not respond to treatment by the chiropodist and the plaintiff was unable to pursue her ordinary occupation from May until October, 1948. Thereafter she received treatment from a dermatologist and the lesions on the bottom of her foot healed leaving scar tissue over the sites of the lesions which the plaintiff testified were sore and which apparently did not have the same amount of tissue underneath the surface as the balance of the area of her sole. The defendant and the plaintiff both testified that the x-rays were administered by placing a metal tube with an opening at the outer end three-fourths inch in diameter against the bottom of the foot at the site of the papilloma. The balance of the foot, according to the defendant, was shielded by a sheath of lead, although the plaintiff had no recollection of the use of the lead shield.

The plaintiff first contended that the evidence was sufficient to warrant submitting the issue to the jury under the doctrine of res ipsa loquitur. The application of res ipsa loquitur, said the court, is necessarily limited in the field of malpractice. The courts have applied it in only a restricted class of cases where the layman is able to say as a matter of common knowledge and observation that the consequences of professional treatment were not such as ordinarily would have followed if due care had been exercised. It cannot be said, as a matter of common knowledge, that the condition which the plaintiff described which included blisters and sores on the soles and tops of her feet and on her shins was caused by the negligence of the defendant. In the absence of expert medical testimony the inference that the condition was proximately caused either by a change in the original condition suffered by the plaintiff or by some new trouble having nothing to do with the radiation was just as reasonable. Under such circumstances, said the court, the res ipsa loquitur doctrine is not applicable.

The plaintiff also urged a reversal on the grounds that the court erred in refusing to permit a chiropodist to testify that in his opinion the injury was an x-ray burn. The record showed that the chiropodist was a graduate of a school of chiropody, that he was licensed in California to treat diseases of the feet and thereby permitted to use x-ray treatments: that he had had courses in anatomy, physiology, histology, bacteriology, physiotherapy and x-ray; that he had spent four and a half years in the Navy attached to an x-ray department of a hospital; that he had studied dermatology and skin conditions. However, it was also shown that the witness had not studied the use of x-rays for treatment; had never in his practice administered x-ray treatments therapeutically; only once had he ever had occasion to distinguish between skin conditions arising from x-ray burns and those resulting from the direct application of heat which was in 1935; he had never treated such a burn; had seen only two cases of x-ray burns in forty years of practice; his use of x-ray in the Navy was for diagnostic purposes only, the therapeutic work having been performed by another department. There was no evidence introduced of any private study on the subject through attendance at lectures, reading or by contact with other men in the field. It is the rule, said the court, that the question whether a person is qualified as an expert is a matter ordinarily addressed to the sound discretion of the trial court, and its ruling on appeal will not be disturbed unless a clear abuse of such discretion is demonstrated. In this case the trial court decision cannot be said to reflect an abuse of discretion.

Accordingly the judgment in favor of the defendant physician was affirmed.—*Bennett v. Los Angeles Tumor Institute, et al.*, 227 P. (2d) 473 (California, 1951).

Laboratory Diagnosis of *Endameba Histolytica*.—Extensive studies were made on methods used for the detection of Endameba histolytica and of their application to the examination of more than 13,000 fecal specimens from 5,048 persons during the past seven years in Chicago and Cook County, Illinois. Combined focal and proctosigmoidoscopic specimens examined within 30 min. after collection, with the use of hematoxylin-stained slides and zinc sulfate flotation, gave optimal results. Variations in the survival time of various strains of E. histolytica in stool specimens at different temperatures were demonstrated. This irregular behavior of E. histolytica necessitates preservation of the specimen if examination is not done within 30 min. Advantages of polyvinyl alcohol and Schaudinn's fixative for hematoxylin-stained slides and the advantages of a 37% aqueous solution of formaldehyde (formalin®) and D'Antoni's stain for flotation were pointed out. Results of stool examination for components other than parasites and bacteria were compiled, and it was shown that they lack value for etiological study but are useful in guidance of symptomatic treatment. Results of surveys for E. histolytica in different groups of persons showed that 4.2% of 237 symptomless medical students and 11.6% of 796 symptomless food handlers harbored E. histolytica. Findings did not reveal so great a difference in percentage of cases of chronic diarrhea between poor patients and those of higher economic status as might be expected. A high proportion (30.6%) of physicians suffering from chronic diarrhea after overseas service had an amebic infection. The approximate proportion of E. histolytica infestations in patients suffering from chronic intestinal disturbances in the Chicago area is estimated as 20% ± 3%.

Iron Metabolism in Human Pregnancy.—Iron tagged with the radioactive isotope Fe^{59} was fed in single doses ranging from 1.8 to 120 mg. to 466 healthy women at various stages of pregnancy, and the uptake of iron determined. As the dosage was increased from 9 to 18 mg. and over, the percentage of the total dose of iron found in the maternal red blood cells decreased, while the amount of iron taken up increased progressively with the dose. As gestation progressed, the uptake of iron increased to the extent that at 30 weeks' gestation and later, three or more times as much iron was absorbed as during the period before the 15th week of gestation, but a three-fold increase in dose from 39 to 120 mg. of iron after the 25th week of gestation produced only a slight increase in terms of milligrams of iron absorbed and utilized. These observations suggest that "preventive" or "protective" iron therapy, even when intensive, may be a relatively inefficient procedure in early gestation. In the latter part of gestation, such protective therapy may be more efficient, but it would seem that single doses of 120 mg. of iron offer little advantage in terms of actual iron incorporated into the maternal red blood cells over considerably smaller doses. The variation in uptake of the fetus with varying dosage did not appear to be greatly different from that of the mother. Relatively little variation in the amount of radioactive iron in the red blood cells of the infant at birth was observed for iron administered at different periods of gestation. The total red blood cell mass of the newborn infant contained on the average about 10% as much radioactive iron as was found in the mother's blood. The ratio of fetal to maternal radioactive iron per milliliter of red blood cells was about one. The uptake of radioactive iron was determined according to parity and period of gestation in

The Association library lends periodicals to members of the Association and to individual subscribers in Continental United States and Canada for a period of five days. Three journals may be borrowed at a time. Periodicals are available from 1940 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied with stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

93 pregnant women. Before the 20th week of gestation, the median percentage uptake was significantly higher in the higher parity groups. In the second half of pregnancy, parity did not influence the uptake. These differences in iron uptake with parity reflect lower iron stores in multiparous women. The normally increased uptake late in pregnancy masked this finding during the latter half of gestation.

Chloramphenicol for Pelvic Inflammatory Disease.—Thirty-two patients, 15 with pelvic inflammatory disease of the nonpuerperal type with pelvic abscess, five with subacute salpingitis without pelvic abscess, nine with infected abortion, two with postpartum sepsis, and one with ruptured appendix were treated with chloramphenicol (chloromycetin®). The causative bacteria were found to be chiefly Escherichia coli, nonhemolytic streptococci, and Aerobacter aerogenes. All but three of the patients had mixed infection. One patient's infection was caused by Staphylococcus albus, and a second patient had beta hemolytic streptococcic septicemia following criminal abortion. Chloramphenicol was administered in divided doses of 0.5 gm. enterally every three hours (total daily dose 2 gm.) for 10 days. Twenty-one of the 32 patients had previously received penicillin, sulfadiazine, and/or streptomycin. There was no response to these agents in 16 cases, a poor and inadequate response in three, and a good response in two, whereas only three of the 32 patients failed to respond adequately to chloramphenicol. The clinical response to chloramphenicol consisted of pronounced symptomatic improvement, usually within 48 hours; rapid disappearance of the peritonitis, and subsequent anatomic regression of the tubo-ovarial inflammatory masses, the patients being ready for exploratory laparotomy within about three to four weeks in the average case. Women who had large pelvic abscesses were treated so effectively with chloramphenicol that posterior colpotomy, with drainage of the abscess, was not necessary for a rapid cure in any of the authors' patients who were treated with this antibiotic from the start.

Intravenously Administered Alcohol as an Obstetric Analgesic.—Intravenously administered alcohol was used alone or combined with meperidine hydrochloride (demerol®) as an obstetric analgesic in 100 women. Alcohol was administered by three general methods. Sixty patients received 7½% alcohol in 5% dextrose in distilled water; the same solution plus meperidine hydrochloride was administered to 27 patients, and 25% alcohol was given to 13 patients. The 7½% alcohol solution combined with small amounts of meperidine hydrochloride is the method of choice. The analgesic effect was excellent and could be altered to suit the obstetrician. There was complete amnesia with the heavier doses and a proportionate degree with smaller doses. Aside from transitory nausea and vomiting, the side effects were negligible. There was no headache, anorexia, or dizziness. There was no maternal death. One infant was stillborn, but there was no reason to believe that the alcohol was at fault. Postpartum bleeding was not increased. The disadvantages of this method are largely those of inconvenience to the attendant. The depth of narcosis must be observed and controlled. Alcohol is of particular value in premature labor and patients with cardiac disease. It appears from trial and theory that the drug should be valuable in eclampsia. Intravenously administered alcohol, as a safe and effective analgesic agent for both mother and child, deserves a place in the armamentarium of drugs applicable to obstetrics.

Exsanguinotransfusion in Hepatorenal Syndrome.—Exsanguinotransfusion was used in the treatment of two severely uremic patients with hepatorenal syndrome following hepatitis. In both patients prior to transfusion the daily urinary secretion was reduced to between 100 and 200 cc. for several days, and the blood urea nitrogen and creatinine were elevated to about 110 and 10 mg. per 100 cc. respectively. In one patient a preliminary dialysis with the artificial kidney was performed. When on the next day the urinary secretion had decreased to 7 cc. and the general condition had deteriorated, 7.5 L. of citrated blood was given and 7 L. was withdrawn. Diuresis started within 24 hr., and the patient recovered. In the second patient two exsanguinotransfusions were performed four days apart. Diuresis began after the first. While these may have been coincidences, it is likely that the introduction of normal blood protein and alkali (sodium citrate) had a beneficial effect in these cases. It is also possible that some toxic substance was removed.

Therapy of Streptococcus Fecalis Endocarditis.—During the treatment of seven patients with endocarditis due to Streptococcus fecalis, Loewe and associates found that this organism was much more resistant to therapy than Str. viridans. Accordingly they evolved a more intensive and prolonged therapeutic program that produced recovery in three patients with Str. fecalis endocarditis. This consisted of the daily intravenous administration of 10 million units of penicillin in Ringer's solution or, in cases of congestive heart failure, in 5% dextrose in distilled water. The volume of the venoclysis did not exceed 1,000 cc. per 24 hr. Heparin was added in a dose of 50 mg. daily to neutralize the local thrombosing influence of the large doses of penicillin, to prevent deposition of thrombotic masses on the valves, and to promote repair of the endocardial lesions. If ineffective blood levels were obtained with this schedule, more penicillin was given along with enhancing agents such as carinamide (staticin®). Treatment lasted not less than five weeks in previously untreated patients and eight weeks in deteriorated or previously treated patients. If the clinical response was unsatisfactory, streptomycin was added for a short period. Supportive measures, such as transfusions, hematinics, and multivitamin preparations were used as indicated. In the presence of congestive heart failure digitalis and mercurial diuretics were given and sodium and oral fluids were restricted. Penicillin was temporarily administered intramuscularly if necessary. The aim of the program was to terminate the infection during the first span of treatment.

Aplastic Anemia Due to Streptomycin.—The authors report on a man, 76, with laryngeal and pulmonary tuberculosis in whom fatal aplastic anemia developed during streptomycin therapy. Death resulted from gastrointestinal bleeding secondary to thrombopenia. This is the third reported case of this complication of streptomycin therapy.

Treatment of Arteriosclerotic Aneurysms of Aorta.—Blakemore describes a new one-stage treatment of arteriosclerotic aneurysm of the abdominal aorta that combines partial constriction of the aorta, intra-arterial wiring, and electrothermic coagulation. Partial constriction is accomplished by the placement around the aorta just proximal to the aneurysm of a slingshot rubber band sheathed in a polyethylene (polythene®) film containing dicetyl phosphate. The elasticity of the rubber band minimizes erosion of the vessel wall, and the irritative action of the polyethylene film produces a fibrous tissue reaction that further protects against subsequent rupture at the site of the band. The aneurysm proper is filled with coils of fine silver wire that impede the flow of blood and provide a framework on which a clot can form. Controlled heating of the wire by means of an electric current produces clotting of the blood near the walls of the vessel where the current is slowest but none in the center where the current is more rapid. This prevents sudden obliteration of the lumen of the aorta with consequent loss of blood supply to the lower extremities. The use of this technique, sometimes with modification, resulted in improvement of the symptoms and roentgenographic findings in eight cases of fusiform aneurysm of the aorta during an observation period of from several months to over a year.

Meconium Peritonitis.—Meconium peritonitis is a sterile chemical or foreign body peritonitis resulting from intestinal perforation and escape of meconium into the general peritoneal cavity. When this occurs during intrauterine life it is usually due to intestinal obstruction caused by stenosis, atresia, volvulus, or constricting bands. Under these circumstances it is not necessarily fatal. Meconium peritonitis occurring at or immediately after birth may be the result of intestinal obstruction or trauma or both. The characteristic signs are early vomiting and progressive distention. Diagnosis is facilitated by roentgen demonstration of dilated intestinal loops and free air in the abdominal cavity. Prognosis is poor, but early recognition and operation before the sterile meconium has become contaminated with bacteria have saved some of these patients. The author reports two cases. In one peritonitis resulted from intestinal obstruction before birth. Operation shortly after birth proved futile because dense prenatal adhesions prevented reconstruction of the intestinal tract. In the other infant perforation was the result of birth trauma, and recovery resulted after early surgical treatment.

Cytology in Diagnosis of Gastric Cancer.—Cytological observations were reported in 875 patients who at one time in their clinical course were suspected of having gastric cancer. Fifty-five (32.8%) of the 168 patients who had cancer showed definite recognizable cancer cells in the smears made from aspirated specimens from the stomach; 31 (18.4%) were suspicious, and 82 (48.8%) were negative. In 25 cases of gastric carcinoma in which lavage specimens were collected and processed promptly, there were correct positive reports in 15 (60%), suspicious reports in two (8%), and definitely false negative reports in eight (32%). It is felt that 60% is about the limit of diagnostic accuracy of any of the lavage methods tried by the authors. Although cytology may be of some help to clinicians it falls far short of being the answer to the existing diagnostic problem. Methods of getting more cell groups from the gastric walls, of concentrating them, and of preparing the material for cytological readings are aspects of the cytological diagnosis of gastric cancer that need further experimental development in the laboratory.

Hormonal Therapy in Breast Cancer.—Forty-eight women between 26 and 75 with cancer of the breast were treated with testosterone propionate. The drug was given in vegetable oil in doses of 100 mg. three or four times weekly or of 50 mg. daily. The therapy period varied from one month to more than one year. Urinary excretion of 17-ketosteroids, gonadotropic hormones, lactogenic hormone and glycogenic corticoids, and urinary creatine-creatinine ratios were measured. Of the 48 patients, 13 (27%) showed objective regression of the lesions. The regression lasted over an average period of 31.3 weeks, the longest being 50 weeks. In the remaining 35 patients there was either progression or no change. In none of the 10 patients aged less than 40 was a good response obtained, whereas a third of those over 40 showed improvement. The length of time the tumor was present before the institution of testosterone therapy was approximately the same for those showing progression as for those who showed improvement. All patients showed the expected increase in 17-ketosteroid excretion as well as the expected decrease in gonad-stimulating hormone excretion. In the patients who improved, there was a decrease of doubtful significance in urinary corticoids and conversely an increase in corticoids in the patients who did not improve. Excretion of lactogenic hormone (prolactin) for both groups of patients increased. In general, the patients who improved showed a decrease in urinary creatine, whereas those who failed to improve showed an average increase in urinary creatine. Seven patients initially had a lower urinary gonad-stimulating hormone value than expected from their age and endocrine status. The authors believe that the cachexia resulting from the extensive disease in these patients induced a sort of initial physiological hypophysectomy with respect to gonad-stimulating hormone. Six of these seven patients failed to respond favorably to therapy.

Refrigerated Homogenous Bone Transplants.—Refrigerated homogenous sterile bone grafts were used for 278 orthopedic operations on 214 patients in the course of three years. Wound infection occurred in four patients (1.4%), and there was loss of the grafts in two (0.7%). In a follow-up study of final results from the refrigerated homogenous bone grafts, 144 patients were traced who had undergone 179 orthopedic operations for a large variety of conditions. On the basis of the number of the operations, results were successful in 80% and unsuccessful in 11%. Fifteen patients had undergone operations too recently for a determination of the results. If four patients in which the failure was unrelated to bone healing are eliminated, the rate of failure can be lowered to 8%. Results were identical with those from the use of autogenous grafts, except that in some instances healing appeared to be somewhat slower. Healing of the grafts took place by a process of invasion, absorption, and replacement similar to that of autogenous bone grafts. With careful technique, homogenous bone grafts may be preserved for long periods of time for surgical use. Such grafts are well tolerated by human tissues, and the risk of infection is no greater than with autogenous grafts. The operation of a bone bank is safe and practical. It offers great advantages to the patient and the surgeon from the standpoint of availability, abundance, and elimination of the necessity of a secondary operation to obtain bone.

Fibrous Dysplasia of Bone.—Four male and five female patients with fibrous dysplasia of bone are reported on. The age of the patients at onset ranged from 15 mo. to 33 yr. Their present ages range from 5 to 48 yr. Experience in these nine cases indicates that the fibrous dysplasia of bone may present a variable clinical picture. There was skin pigmentation of the café au lait type in five of the patients. Sexual precocity was seen only in the two patients with the full syndrome complex, *i. e.*, lesions of the skin, bones, and endocrine system. The number of bones involved ranged from one to 15. The alkaline phosphatase was elevated in two patients. There was only one patient who did not have a fracture at some time during the period of observation. Five of the patients showed deformities ranging from mild coxa vara to severe genu varum. In adults there may be rather extensive lesions in more than one bone without symptoms or serious impairment of function. In five of the nine patients curettage of the bone lesions and packing of the areas with bone chips were carried out. In the three patients with relatively small lesions results were good. In the two patients with large lesions where the abnormal tissue could not be entirely removed, the chips were absorbed on three occasions. In one patient osteotomies were performed to correct the severe bowing. The bone at the site of osteotomy united, but the deformities have begun to recur above the level of the osteotomies. In the usual case a summation of clinical, roentgenographic, and microscopic findings is desirable for diagnosis of this disease. When islands of cartilage are present, the diagnosis can be made on the basis of the gross or microscopic examination alone.

Effect of Combinations of Antibiotics.—In vitro and in vivo tests were made of the sensitivities of seven strains of Pseudomonas aeruginosa and four strains of Proteus vulgaris to various concentrations of aureomycin, chloramphenicol, penicillin, dihydrostreptomycin, and terramycin, singly and in combination. The in vitro tests on Ps. aeruginosa showed that in certain combinations the bactericidal properties of the drugs were increased. There was a pronounced reduction in concentration of antibiotic required for the aureomycin-terramycin and the chloramphenicol-terramycin combinations. A combination of penicillin with dihydrostreptomycin resulted in a reduction of the bactericidal concentrations required of each, but these were still relatively high. The triple combination of aureomycin-dihydrostreptomycin-terramycin also showed great reduction in required concentration; however, this combination is not recommended, since aureomycin and terramycin are effective without dihydrostreptomycin, which leads rapidly to resistance in the organism. The results with penicillin in dual combinations did not appear to justify its trial in triple combinations. There was one case of apparent drug antagonism; i. e., the chloramphenicol-penicillin combination required higher concentrations of the antibiotics than when the drugs were used alone. In the in vitro sensitivity tests on the four strains of Ps. vulgaris aureomycin-dihydrostreptomycin and dihydrostreptomycin-terramycin showed significant decreases. Triple combinations were again less promising, with the exception of aureomycin-dihydrostreptomycin-terramycin, which required a much smaller concentration than when the drugs were given alone. No antagonism between the drugs was noted in these combinations. The most promising in vitro combinations for Ps. aeruginosa were also effective in vivo. The dual combinations were especially effective. Treatment with an aureomycin-chloramphenicol-terramycin combination was tried without particular benefit. Antibiotic combinations including dihydrostreptomycin were used for in vivo experiments with P. vulgaris. For some unknown reason a mixed culture of P. vulgaris strains that were individually resistant to dihydrostreptomycin *in vitro proved to be very sensitive to dihydrostreptomycin* in experimentally infected mice. The authors suggest that in each case the drug or combination of drugs used should be determined by preliminary laboratory investigation.

Observations on L. E. Cell.—Smears of heparinized blood or marrow from 115 patients with various diseases were examined for L. E. cells. The cells were found in 14 of 21 cases of disseminated lupus erythematosus but were not observed in any other condition (i. e., periarteritis nodosa, acute rheumatic fever, rheumatoid arthritis, thrombopenic purpura, multiple myeloma, and dermatitis medicamentosa). The number of L. E. cells and rosettes found on examination of the heparinized blood buffy coat smears roughly paralleled the number occurring in the heparinized marrow buffy coat preparations from the same patient. In the patients with acute disseminated lupus erythematosus who were treated with pituitary adrenocorticotropic hormone (ACTH) or cortisone, the number of L. E. cells and rosettes present in the blood decreased but did not disappear during therapy. There was no apparent relation between the total white blood cell count and the number of L. E. cells seen in the buffy coat smears. It was further demonstrated that L. E. cells may be formed in the absence of anticoagulant. The authors did studies to determine the period of time required for the formation of L. E. cells. Their formation was completely inhibited by low temperatures, and after blood had been chilled at least 10 min. of incubation at 37 C. was required for them to form. In all the specimens incubated at 37 C. for one minute or longer, extracellular material closely resembling the homogeneous, purplish mass seen in L. E. cells was observed. Incubation of heparinized blood for 15 minutes at 37 C. appeared adequate for optimal L. E. cell production.

Accident Proneness in Multiple Sclerosis.—Bennett reviews the literature and discusses three cases from his own medicolegal records on the relationship between trauma and multiple sclerosis. Although medical evidence is against the theory that trauma causes or exacerbates multiple sclerosis, compensation courts are granting large awards to such claimants. Reasons for this seem to be the failure to understand the course of the disease, with its spontaneous remissions and progressive pathology; the peculiar type of personality changes, manifested in euphoria, overconfidence, and poor judgment; the symptoms of motor paresis, ataxia, and disturbed equilibrium. These factors make patients with multiple sclerosis more prone to have accidents and to accept them as causing or aggravating their symptoms. The efforts of an adroit attorney, together with a sympathetic judge, enable the claimant often to obtain a large, unjustified award for total permanent disability. There is increasing need for a unified medical opinion to guide courts in these decisions. Neurologists have too often certified that an accident aggravated existing symptoms. The hypothetical question, a favorite legal device, undoubtedly biases opinion, since it can be and frequently is so worded that the expert has to admit that trauma as an etiological factor lies within the realm of possibility. A free, unbiased statement of the medical evidence should replace the hypothetical question. Expert witnesses, drawn from a panel of qualified neurologists, should replace the present method of retaining one or more experts expected to render favorable opinions to the side retaining them.

Antibiotics in Pertussis.—The comparative clinical effectiveness of streptomycin, aureomycin, chloramphenicol, and terramycin was studied in 160 cases of uncomplicated pertussis. Streptomycin appeared to be of only questionable value, but the remaining three antibiotics were equally effective in shortening the duration of the whooping stage. Chloramphenicol and terramycin also significantly shortened the duration of fever. The effective minimum dose for aureomycin, chloramphenicol, and terramycin was 50 mg. per kilogram of body weight per day. At this dose the antibiotics were well tolerated. There was no therapeutic advantage in giving the drugs in combination. In patients seen after this study there seemed to be increased bacterial resistance to these antibiotics. The authors conclude that the ideal drug for the treatment of pertussis has not been developed.

Rh Factor and Cerebral Palsy.—The authors studied 98 children with cerebral palsy and their mothers to determine whether isoimmunization to the Rh or ABO blood factors played an important role in the production of this condition. The percentage of Rh-negative mothers and Rh-positive children in the group was approximately the same as found in the general population, but three of the children had erythroblastosis fetalis, a somewhat higher incidence than in the general population. ABO blood group incompatibility was found in a lower proportion of these families than in families with normal children. The authors conclude that maternal isoimmunization to the Rh factor plays only a slight role in the etiology of cerebral palsy.

Twin Fetuses in Fetu.—This is a report of a very unusual type of retroperitoneal teratoma, consisting of twin fetuses, occurring in a newborn infant. The infant was admitted to the hospital at the age of two days because of regurgitation and the presence of a fist-sized abdominal mass. Roentgenograms of the abdomen showed a moderate amount of amorphous bone and an almost complete fetal skeleton in the center of the mass. Surgical excision was performed, and the mass was found to consist of two membranous sacs containing two partially developed fetuses. Recovery was complete following operation, and the child developed normally during a three and one-half year observation period. A fetus in fetu does not arise from fertilization of an ovum within a child. Instead it represents a splitting off of cells from a developing embryo, the growth of which produces a teratoma. Complete excision of the entire growth, including the membranes, is essential for cure, since remnants invite local recurrence or metastatic spread. Radiation therapy is not curative in these cases.

Penicillium Infection of Urinary Tract.—This paper concerns the occurrence of a Penicillium mold in man as a pathogen. The patient was an entomologist, 56, who for many years had had episodes of colicky right flank pain, coming on suddenly and sometimes lasting for several days. The pain, usually beginning over the kidney region and radiating down the course of the ureter, was accompanied by mild fever and malaise and was followed in a few hours by the passage of balls of pink material in the urine. Following this there was a remission of the fever and no further symptoms until the occurrence of another attack, some months later. The attacks seemed to be more frequent in fall and winter. The pink material in the urine was identified by the authors as a large mass of mycelium. Cultures from the kidneys obtained by ureteral catheterization revealed a mold that was present only in the urine from the right side. Pure cultures of the mold were identified as Penicillium citrinum, one of the 200-odd species of Penicillium. There was little evidence that serious kidney damage had occurred from this unusual infection over the past 12 years. There was only moderate reduction in renal function, and the pyelographic evidence of pyelonephritis in the affected kidney was not pronounced. This particular Penicillium produced little if any antibiotic substances on culture. It possibly produced a weak antibiotic in vivo, as the urinary tract had remained sterile. No chemotherapeutic agent has been found to which this fungus will respond. The patient died elsewhere, and cultures taken at autopsy showed Penicillium in the bladder and right kidney.

Vagotomy and Pyloroplasty for Duodenal Ulcer.—Eighty-five to 90 per cent of patients with duodenal ulcer can be managed satisfactorily by medical measures. In intractable or complicated cases gastric resection yields good results in about 90% of patients. However, Dorton and Webb feel that the mutilating nature of the procedure, together with its magnitude, risk (2 to 3% mortality), and a 5 to 10% incidence of marginal ulceration, justifies the search for a simpler and safer method. They feel that vagotomy combined with pyloroplasty is such a method. They selected pyloroplasty as the drainage procedure to accompany vagotomy for the following reasons: 1. It relieves pylorospasm, which is probably a contributing factor in the production of duodenal ulcer. 2. Pyloroplasty permits direct inspection and local removal of the scarred ulcer area. 3. The approach can be used to control a bleeding vessel. 4. Pyloroplasty has the advantage of Billroth 1 procedure: anastomotic ulceration cannot occur. 5. Pyloroplasty prevents strictures at the outlet of the stomach as the ulcer heals. It also permits ready emptying of the stomach during the immediate postoperative period, when the stomach is temporarily atonic from the recent gastric neurectomy. 6. Pyloroplasty is much simpler to perform than gastroenterostomy and has a lower morbidity. 7. Pyloroplasty does not alter the basic anatomic arrangement of the stomach. 8. Finally, since pyloroplasty alone will cure only 20% of ulcers, the curative effect of vagotomy would be less obscured than if gastroenterostomy, which cures 70 to 80%, was used. Twenty-two patients with proven intractable or complicated duodenal ulcers were treated by vagotomy and pyloroplasty. Twenty-one (95.4%) of these patients have had excellent results.

Aureomycin in Chronic Amebiasis.—In vitro studies demonstrated that aureomycin hydrochloride killed the trophozoites of Endameba histolytica in concentrations as low as 50 γ per cubic centimeter. Although this effect was undoubtedly in part the consequence of an alteration of bacterial flora, there was evidence that aureomycin also directly attacked the amebas. Twenty patients with amebiasis, 10 with chronic amebic dysentery, six amebic cyst passers or carriers, and four with amebic hepatitis or amebic abscess were treated with aureomycin hydrochloride by mouth. The dose given was 0.5 gm. every six hours for 10 days. In the 10 patients with chronic amebic dysentery the parasites usually disappeared from the stools within 24 hr. after the first dose, although, in two patients, 48 to 72 hr. of treatment was required before the parasites disappeared. Seven of the 10 patients remained asymptomatic for three to 14 mo. after treatment was discontinued. One patient had recurrent symptoms, another required two courses of treatment before his symptoms disappeared. In a patient with regional ileitis paralytic ileus developed during aureomycin therapy and required surgical excision of the involved ileum. After 24 to 72 hr. of treatment cysts could no longer be observed in the feces of the six patients who had passed cysts of Endameba histolytica in their feces before treatment. No parasites were found in formed or purged stools of any of these patients for an average of six months after treatment. Only one of the three patients with amebic hepatitis became asymptomatic and free of amebas on stool examination after a single course of aureomycin. One other patient, with liver abscess, showed no symptomatic benefit from aureomycin, although the amebas disappeared from his feces. At present it appears that aureomycin should not be used alone in the presence of hepatic amebiasis but should be supplemented by emetine hydrochloride or chloroquine phosphate or both. No serious toxic effects of aureomycin were noted, although it caused minor gastrointestinal disturbances in several patients.

Rickettsialpox in Boston.—The natural occurrence of rickettsialpox is reported in a housewife, 46, in Boston. The diagnosis was established by the typical clinical and laboratory observations, including a significantly elevated complement fixation titer. Systemic symptoms were noted three days after detection of the primary lesion, an area of induration and erythema with a central black crust on the dorsal surface of the right thenar eminence. Temperature was restored to normal after six days of fever, the highest recorded level reaching 103 F. Severe frontal headache was one of the chief complaints. An irregularly scattered, discrete, slightly erythematous maculopapular eruption over the chest, abdomen, and back appeared on the fourth day after fever was first noted. During both the acute and the convalescent phases of the illness, results of tests for heterophil antibody were negative. The complement fixation titer rose from zero during the acute phase of illness to a level of 1:320 during convalescence, three weeks after the appearance of the primary cutaneous lesion and 19 days after onset of fever. The patient recovered promptly without specific treatment. This is the second naturally occurring case of rickettsialpox diagnosed in Massachusetts. It probably indicates a second focus of natural infection within the city of Boston.

Aureomycin in Acute Gonorrhea.—Sixty-three Negro male patients between the ages of 14 and 56 with acute gonorrhea were treated with aureomycin. A single capsule containing 500 mg. of aureomycin was given initially and a second 500 mg. capsule six hours later. The clinical follow-up showed that the course of the disease was strikingly uniform in these patients. Within 24 hr. bacteriologic smears and cultures were negative in most cases, and the thick, purulent discharge had disappeared completely, although some patients still had a thin, watery discharge that was free of gonococci. After 48 hr. the urethral discharge had completely disappeared. Sixty patients (95.2%) with adequate clinical follow-up were cured; that is, there were negative smears and culture and no clinical symptoms. The remaining three patients were therapeutic failures. With the dose used toxic reactions were minimal and high urine levels of aureomycin were obtained, which persisted for at least 48 hr. in three of four patients. The results showed that aureomycin is as effective as penicillin in the treatment of acute gonorrhea. Aureomycin possesses the following advantages: ease of administration; minimal toxicity limited to the gastrointestinal tract; little or no increased drug resistance of the gonococci; beneficial effect in concurrent gram-negative bacterial urinary tract infections sometimes associated with gonorrhea. Aureomycin should be considered one of the agents of choice in the treatment of acute gonorrhea.

Duodenal Obstruction in Newborn Infants.—Five newborn infants with obstruction of the duodenum were operated on during the past year. The obstructing mechanism was extrinsic in three instances and intrinsic in two. Two patients died, one on the 11th postoperative day, and the other, who was operated on twice, died 24 hours after the second operation. The three other patients made an uneventful recovery. Complete obstruction of the duodenum is a fatal condition unless an early diagnosis is made and adequate surgery is instituted. Vomiting, dehydration, and constipation in the newborn, with a distended mass in the epigastrium and a flat hypogastrium should lead the physician to suspect the true diagnosis. Roentgen examination will reveal a dilated stomach and proximal duodenum, with failure of barium to pass into the jejunum at the end of six hours. Intestinal gas patterns will be absent if the obstruction is complete. Proper preoperative and postoperative care, with replacement of fluids, electrolytes, and blood, and the use of antibiotics will definitely influence the mortality rate.

Histoplasmosis.—The first case of histoplasmosis in West Virginia is reported. The patient was a white female aged 21 months. Physical examination revealed moderately enlarged anterior and posterior cervical lymph nodes. Both the liver and the spleen were palpated two fingerbreadths below the costal margin. The temperature was of the spiked septic type. Tuberculin tests gave negative results. Positive cultures of Histoplasma capsulatum were obtained from the feces, throat, and urine before death, making diagnosis possible before autopsy. The mouth was suspected to be the portal of entry. Cultures obtained of a lymph node taken at autopsy showed the pathogenic agent. A histoplasmosis complement fixation test gave positive results in a titer of 32. A lowered total serum protein level was noted. Treatment, including aureomycin therapy, was ineffective.

*Results of Ligation of Inferior Vena Cava in 50 Cases of Irreducible Cardiac Decompensation. E. Donzelot, F. d'Allaines, R. Heim de Balsac and others.—p. 239.

Ligation of Inferior Vena Cava.—Ligation of the inferior vena cava was performed on 50 patients with irreducible cardiac decompensation, of whom 38 had mitral lesions, nine had hypertension, two had aortic lesions, and one had myocardial infarction. Ten patients died within the first two postoperative weeks; in four of them the operation was performed as a last resort. The indication for the operation was apparently erroneous in one patient with calcified aortic stenosis and pulmonary edema, and death resulted from accidents in the remaining five patients. Immediate satisfactory results were obtained in 38 of the 40 surviving patients. Orthopnea and nocturnal paroxysmal dyspnea disappeared, but the objective element of the clinical picture were influenced to a lesser degree. Two patients were not benefited by the operation. Of the 38 who were benefited five showed only slight and transitory improvement, while 33 showed significant and more persistent improvement during a follow-up period of four to 17 months. Twenty-one of the 33 patients were able to lead fairly normal lives: seven returned to factory work, five had to make an occupational change, and nine were able to do housework. In all these patients the persistent disappearance of the functional disturbance was the dominant feature. Nine patients died within three to 13 months after the operation, of whom four had been improved by the operation and one had resumed his former occupation. Death resulted from hemiplegia in four, from cardiac decompensation in two, from nephritis in two, and from repeated surgical intervention in one. Ligation of the inferior vena cava is to be considered only a palliative operation, but it may bring about persistent relief. The best results were obtained in patients with definite cardiac decompensation who still responded to rest and cardiotonics, i. e., in patients whose myocardium is still capable of recovery. With improved surgical technique (transperitoneal approach) and with less early postoperative heparinization the mortality rate should decrease. Conservative and surgical treatment do not exclude one another, but the latter may complete the first if performed at a favorable time in carefully selected cases.

*Tuberculous Meningitis Cured by Streptomycin. P. Cantonnet Blanch, A. Pérez Scremini and E. Katz.—p. 18.

*Treatment of Purulent Meningitis in Infants Without Use of Intraspinal Route: Results Obtained in Montevideo. J. Bonaba and J. A. Portillo. —p. 33.

Tuberculous Meningitis Cured by Streptomycin.—A boy, 10, in the course of three years after occurrence of primary tuberculous infection successively had tuberculous pleurisy, ascites, and bilateral spread of pulmonary tuberculosis, which were controlled by the administration of dihydrostreptomycin, in a daily dose of 1 gm. up to a total dose of 40 gm. Four months later, the tuberculous meningitis developed. The diagnosis was confirmed by the positive results of cultures and inoculation of the cerebrospinal fluid in animals. The disease was cured by dihydrostreptomycin, given intramuscularly in a dose of 2 gm. daily and, later on, of 25 mg. three times a week, up to a total dose of 372 gm. in six mo. The intraspinal dose was 50 mg. at four day intervals, up to a total dose of 1.80 gm. for the first few weeks of the disease. The drug was well tolerated by the intramuscular route but not by the intraspinal route. Cure has been maintained up to the present (four months after treatment).

Purulent Meningitis in Infants.—Bonaba and Portillo report good results from a combined treatment of sulfadiazine by mouth and penicillin and streptomycin intramuscularly in 28 cases of purulent meningitis. Most of the patients were infants and young children. At the beginning of treatment the daily doses per kilogram of body weight should be 50 mg. of sulfadiazine, 50,000 units of penicillin, and 50 mg. of streptomycin. Further doses should be adjusted to the clinical course of the disease, the changes of the cerebrospinal fluid, and the levels of the aforementioned drugs in the cerebrospinal fluid. In the cases reported there were no complications, sequelae, or deaths. The cerebrospinal fluid promptly returned to normal, and the disease was promptly controlled.

*Differential Diagnosis: Gas in Tissues. G. Sättler.—p. 56.

*New Basic Concepts and Points of View Concerning Pathogenesis and Therapy of Urogenital Tuberculosis. A. Gütgemann.—p. 83.

Differential Diagnosis of Gas-Forming Infections.—The following classification of infections associated with gas in the tissues is suggested: infections associated with air introduced by foreign body, abscess containing gas, gas phlegmon, true gas gangrene of muscular tissue, and putrid gangrene associated with gas. Roentgenologic demonstration of gas in the tissues is of considerable aid to early diagnosis and differential diagnosis. Circular translucent areas of gas above a horizontal liquid surface, particularly in the neighborhood of a causative foreign body, are characteristic of an abscess containing gas. A coarse or fine mottled arrangement of air bubbles in the interstitial areas characterize the gas phlegmon, and feathering of the muscular fibers is to be considered as definite proof of gas gangrene. Putrid gangrene with secondary formation of gas is characterized by a more spongelike structure. There is not always a sharp transition between the roentgenologic picture of putrid gangrene and that of true gas gangrene, mainly because the two frequently occur together. The roentgenologic picture is also an aid in the exact localization of gas gangrene in cases in which proximal to the origin of the gas formation the blood supply of still healthy tissue has been stopped by the diffusion of gas under high pressure. In addition, roentgenography may be helpful in revealing gas gangrene in the deep tissues in the absence of clinical signs. Roentgenologic examination, therefore, should be performed in all doubtful cases.

Urogenital Tuberculosis.—According to Gütgemann, tuberculosis of the urinary system is to be considered frequently as an intermediate stage in the course of generalized tuberculosis. Insufficient consideration of the general condition of resistance, the phase of the disease, and the stage of the tuberculous changes of the tissues are the reasons why definite recovery frequently is not obtained with nephrectomy. Early nephrectomy is still indicated when the tuberculous kidney constitutes a predominant focus, with extensive destruction of its parenchyma and loss of function, thus becoming the starting point of a progressive tuberculosis of the urogenital system. Surgical intervention is not advisable when (1) postprimary tuberculosis is still developing, (2) there is late primary infection with a rapid course, (3) hematogenous dissemination has occurred only recently, (4) there is the possibility of the subsequent occurrence of destructive foci on the as yet uninvolved side, and (5) resistance is not yet consolidated or there is progressive tuberculosis of other organs. Preparatory medical treatment is required in all these cases as well as in those of recent exudative tuberculosis of the kidney. It is imperative to reduce the exudative parenchymatous tuberculosis to a productive-fibrous phase by conservative helio-aerotherapy and to use surgical treatment only after the general resistance has improved and the unilaterality and destructive form of the focus has been established. On the other hand, early nephrectomy is indicated in patients with

symptoms on one side only, progressive destruction of parenchyma, toxic lesions of the other kidney, rapidly progressive course of tuberculosis of the bladder and the genital organs, mixed infections, intermittent obstruction and closed pyonephrosis, small focus on the other side, and severe bacilluria. Nephrectomy is less urgent in cases in which a purely parenchymatous nondestructive form of renal tuberculosis may be suggested by mild bacteriuria and albuminuria; in tuberculous nephritis, and in patients with small papillary foci, mild pyuria, good renal function, and no cystitis. Foci in the male genital organs deserve greatest consideration and simultaneous treatment, but radical intervention is indicated only for caseating, disintegrating and disseminating unilateral foci in the seminal vesicles and in the prostate.

Penicillin-Resistant Bacterial Endocarditis.—This is a report of four patients with subacute bacterial endocarditis due to penicillin-resistant organisms (Streptococcus faecalis in three and Str. viridans in one). Several types of therapy were tested in each patient. Separate courses of streptomycin and of aureomycin in two patients and of chloramphenicol in a third were all unsuccessful. A combination of penicillin and aureomycin failed to control the fever in one and produced toxic symptoms in another. In three the infection was apparently controlled by a combination of 20 million units of penicillin and 4 gm. of streptomycin daily for at least six weeks. One of these patients died later from heart failure; the other two are alive and well, except for vestibular damage. The fourth patient died from heart failure on the fifth day of treatment, and, although clinical response was prompt, necropsy indicated that infection had not been eliminated. Previously this patient had relapsed after smaller dosages of penicillin and streptomycin given together. The infecting organism was highly resistant to streptomycin. In vitro, the bactericidal action of penicillin on the two organisms so tested was accelerated by the addition of streptomycin and retarded by the addition of aureomycin. In one patient tooth extraction during the prophylactic use of 2 million units of penicillin daily for six days was followed by subacute bacterial endocarditis due to a penicillin-resistant organism.

Sympathectomy for Hypertension.—Since 1945, 35 patients with severe essential and malignant hypertension have been treated by thoracolumbar sympathectomy at Hammersmith Hospital. All these patients met the following criteria: (1) age under 55 years, (2) blood pressure over 200/100 mm. of mercury, with diastolic pressure capable of being reduced at least 20 mm. of mercury by bedrest or sedation, (3) symptoms referable to hypertension present, (4) renal function adequate, (5) cardiac function compensated, and (6) residual disability from any previous cerebral vascular accident absent. Transpleural sympathectomy was performed with resection of the splanchnic nerves and of the ganglionic chain from the sixth thoracic ganglion to the first lumbar ganglion inclusively. Follow-up studies two to 51 months (average 18 months) later revealed that only 25% of the patients had maintained a significant fall in blood pressure but that 66% of them had been relieved of incapacitating symptoms and had returned to work. The author concludes that sympathectomy improves the prognosis of malignant hypertension and is a valuable procedure for a limited but definite group of patients with hypertension.

Poliomyelitis and Diphtheria Immunization.—During an epidemic of 98 cases of poliomyelitis in Belfast an attempt was made to correlate the site of paralysis with previous inoculations of diphtheria toxoid. All but 10 of the 98 children showed paralysis. In two children poliomyelitis developed within one month after immunization against diphtheria. One of them was injected with 0.5 cc. of alum-precipitated toxoid in the right hip, and paralysis of the right leg developed after eight days. The other patient received 0.5 cc. of purified diphtheria toxoid, alum-precipitated, in the left arm, and facial paralysis developed 23 days later. In three children poliomyelitis developed within one to three months after the immunization against diphtheria. These patients had had injections in the arm, but paralysis did not develop in the arms in which injection was made, two of the patients having facial paralysis and the third having paralysis of both legs. In the 28 children in whom paralysis developed more than three months after inoculation, the injection, with one exception, had been given in the arm. In this group paralysis affected the arms less than the legs. In a group of uninoculated children under 2 years of age, paralysis affected the arms almost as frequently as the legs. This is in contrast to the usual preponderance of leg paralyses and shows the spontaneous variations in the site of involvement. An association between site of inoculation and site of paralysis was not observed after 6,250 inoculations of purified diphtheria toxoid, alum-precipitated, in children aged less than 9 years affected by the poliomyelitis epidemic. This limited experience does not prove that the site of inoculation and the site of paralysis in poliomyelitis are unrelated, but the author's experience suggests that purified diphtheria toxoid, alum-precipitated, is a relatively inocuous antigen as far as induction of poliomyelitis in the inoculated limb is concerned.

*Significance of Hyperaminoacidemia in Hypoproteinemia. G. Labo' and T. Franco.—p. 133.
*Lack of Potassium, "Determining Factor" of Cardiovascular Insufficiency in Diabetic Coma. A. M. Bertolini and L. Scapellato.—p. 173.

Aminoacidemia in Hypoproteinemia.—Labo' and Franco determined the amount of amino acids in the blood of 25 patients with grave hypoproteinemia complicating different diseases. The level was high in all cases. Often the figures were twice the normal values. The test was repeated when hypoproteinemia diminished or increased. The amino acid level varied inversely as the concentration of proteins in the blood. The deaminizing power of the liver was tested in 15 patients and in 10 controls by the intravenous injection of 100 cc. of a 5% casein enzymatic hydrolysate solution. This power of the liver was normal in eight of the hypoproteinemic patients and diminished in seven. In the latter it became normal when the proteins in the blood became normal. In six patients disturbances in the metabolism of iron and vitamin B_2 paralleled the course of hypoproteinemia. This suggests that (1) hyperaminoacidemia in hypoproteinemia is due to disorders of the cellular respiratory enzymes, either independent of, or secondary to hypoproteinemia and (2) that the changes in the velocity of deamination in the liver are due to enzymatic disorders and not to liver insufficiency.

Hypopotassemia in Diabetic Patients in Coma.—According to Bertolini and Scapellato, intractable shock, which often follows diabetic coma controlled by insulin, is due to lack of contractility of the myocardial fibrils from insufficiency of serum potassium. The authors emphasize the importance of serum potassium in regulating muscular contraction and point out the causal factors of hypopotassemia in the course of diabetic coma. As proof of the role of hypopotassemia in this condition they cite the typical myocardial lesions from hypopotassemia reported in the literature, the regression of electrocardiographic changes in diabetic coma following the administration of potassium, and the control of diabetic coma by the administration of potassium.

Paralysis in Two Stages in Poliomyelitis.—In about 5% of the cases of poliomyelitis, paralysis may develop in "two stages," i. e., new peripheral paralyses may develop within eight days to one month after the first appearance of paralysis and may be localized in parts of the body not previously involved. The authors recently observed five cases of this type. One was that of an adolescent, 17, with flaccid quadriplegia and definite meningeal syndrome. Within one month, when the acute phenomena had disappeared and the patient was able to move his lower extremities somewhat, he experienced an attack of bulborespiratory type with tracheobronchoplegia and paralysis of the intercostal muscles and of half of the diaphragm. These symptoms subsided partially, and the patient survived. A second patient, 15, with flaccid quadriplegia and total respiratory paralysis, had been placed in a mechanical respirator for two months, when suddenly he presented a paralysis of the hypoglossal nerve followed by fatal coma. The authors' five patients were treated with convalescent serum and large doses of pteroylglutamic acid (folic acid); they were also given roentgen irradiation of the spinal cord, and two of them received large doses of cortin. None of this therapy prevented the "second stage" of paralysis. In most of the patients of this type reported on in the literature, the upper levels of the spinal cord were involved. Seventy-six per cent of the patients had severe quadriplegia or respiratory paralysis or both. Intercurrent infections, such as chickenpox and infectious pulmonary complications, in patients with respiratory paralyses seem to predispose to this particular type of paralysis. The pathogenesis remains doubtful. Although the possibility of a relapse or a second attack may be considered, one must admit that the virus is capable of persisting in the nervous system of certain patients with poliomyelitis or of reinfecting the organism by the endogenous route. Weakened resistance due to intercurrent infection and prolonged presence of the virus in the fecal matter may play some part.

Routine BCG Vaccination of the Newborn.—In the course of the first six months of 1950, BCG vaccination was given to 650 infants in a maternity ward. Only premature infants whose weight was less than 5 lb. (2,267.96 gm.) and those whose mothers refused vaccination were not vaccinated. Within six weeks after the vaccination 361 of the 650 infants were subjected to a skin test, and the reaction to it was positive in 97.78%. Six months later a control test could be performed on only 154 children. The cutaneous reactions were positive in all the children, including two who had negative reactions to the first test. Thus the purpose of the vaccination, to induce the appearance of a cutaneous allergy, was fully achieved. Significant reactions in the lymph nodes in the vaccination area occurred in only eight children. "Becegitis" is the term that was coined for this accident. Recovery without fistulization occurred in four instances, and fistulization occurred in three, in one of which Koch's bacillus was demonstrated. A large left carotid lymph node was observed in the eighth child. An incision was made, and pus was removed that resembled the pus of a cold abscess. The lymph nodes in the right subclavicular region and those in the right masseter muscle were also enlarged. There was a highly positive reaction to a repeated skin test. The child took a downhill course and died. Koch's bacillus could not be demonstrated. Accidents of this type were never observed in adults. Since a regular follow-up of the vaccinated children during the first years of life is not possible practically although it is imperative, the authors doubt the expediency of routine BCG vaccination in newborn infants in a maternity ward, not so much because of the risks involved, which are minimal, but because of the danger of discrediting an excellent method of prophylaxis, the systematic employment of which should be limited to adolescents and adults who still have negative reactions to tuberculin skin tests, and to children in the school age.

- •Thirty-Five Cases of Brucellosis Treated with Aureomycin. M. Y. Mazaré and O. Bertheas.—p. 375.

Bacteriologic Dependence on Streptomycin.—Five patients between 25 and 45 with tertiary pulmonary tuberculous lesions are reported on. In four of these patients two distinct successive clinical phases were observed during treatment with streptomycin. In the first phase, which varied in duration, the condition of the patients improved with administration of streptomycin. During the second phase the condition of the patients became worse when the drug was given, and their tuberculous lesions progressed rapidly. In this stage the tubercle bacilli showed in vitro a relative dependence on streptomycin: instead of being inhibited by the antibiotic, they grew more abundantly and more rapidly when streptomycin was added to the Youmans medium. In one patient the first course of treatment produced an exacerbation of his condition, and an absolute dependence of Koch's bacillus on streptomycin was demonstrated in vitro: the bacillus could be isolated in Youmans medium only when streptomycin was added. In this patient the two clinical phases that were observed in the four other patients could not be differentiated, because of the rapid development of the bacterial dependence in the ulcerative-caseating lesions within three weeks. Resistance to streptomycin when once acquired is permanent, but dependence is temporary, and the strains may lose their dependence more or less rapidly, provided that contact with the antibiotic is discontinued. For long periods of time bacterial resistance may not be associated with dependence, despite continued treatment with streptomycin. Bacterial resistance to streptomycin observed in vitro is to be considered a danger signal, which requires immediate discontinuation of treatment. Sputum cultures should also be made then, since resistance to streptomycin may quickly be followed by dependence. Paraaminosalicylic acid given by mouth and continued administration of streptomycin in effective doses frequently but not always prevents resistance. The authors advise against alternative courses of treatment with paraaminosalicylic acid and streptomycin and against isolated or repeated courses of treatment with 20 to 40 gm. of streptomycin alone, which they consider as a definite means of building resistance of the bacilli to the antibiotic. Intramuscular administration of a total dose of 80 to 120 gm. of streptomycin combined with oral administration of paraaminosalicylic acid given by mouth in daily doses of 15 to 25 gm. is recommended.

Aureomycin in Brucellosis.—Thirty-five patients, 22 men, 11 women, and 2 children, with brucellosis were treated with aureomycin on a daily dose of 0.10 to 0.25 gm., which was increased gradually to a maximum of 2 to 3 gm. in adults and maintained for two weeks. The total dose varied from 24 to 55 gm. Clinical recovery was rapid and spectacular in 33 patients. Headache subsided within four to five days, the spleen became smaller within 10 days, and myalgia and arthralgia disappeared within 15 days. The patients were apparently cured within 15 to 20 days. Two patients were therapeutic failures. Untoward reactions to the drug consisted of nausea, vomiting, pruritus ani, and malaise but were never so severe that discontinuation of treatment was required. Late results of treatment were less satisfactory than early results. Of 22 patients, nine who had been followed up for one to eight months made a complete and definite recovery. In two patients symptoms reappeared in an attenuated form after the patients' discharge from the hospital and persisted for three weeks, to be followed by recovery, which then was maintained for four and seven months respectively. Eleven patients had true recurrences, with refractory symptoms requiring repeated hospitalization in three instances. The authors believe that aureomycin induces improvement rather than a definite cure of brucellosis. Prognosis is more favorable in young patients, provided that large doses (4 gm. daily from the start of the treatment) may be administered for 30 days (total dose 120 gm.) and that treatment is instituted early. The systematic combination of aureomycin therapy with vaccine therapy seems to be justified.

Electric Convulsion Therapy with Tantalum Plate in Skull.—This is the first report of electric shock therapy in a patient with a metal plate in his skull. The patient was a man, 30, with a depressive state following severe head injury. Skull x-ray plates showed a large metal plate in the left frontoparietal region and a retained metallic fragment in the vault near the right border of the plate. There was some doubt as to what might happen if electroshock therapy were given to a patient with a tantalum plate in his head, but the patient agreed to the treatment and 7 electric convulsion treatments were given without untoward effect. Complete recovery ensued. The author believes that there will not be many cases like this one; but with the increase of extensive brain surgery it is possible that from time to time other patients will be seen for whom electric convulsion therapy might be withheld because of doubts about its safety, when, if given, it would perhaps produce speedy relief.

Risks of Gastroscopy.—The risks associated with gastroscopy were assessed by means of a questionnaire sent to 40 gastroscopists. Seventy-five accidents with 32 deaths were reported following 49,000 gastroscopies. Five additional accidents with three deaths were reported, but the corresponding number of gastroscopies was not known. Fifty-four, i. e., two-thirds of the accidents were perforations of the esophagus, which usually occurred in the upper esophagus or hypopharynx with the use of the Hermon Taylor gastroscope. Most of them occurred in women over 50, and the risk in this age and sex group was estimated to be nine or 10 times that in men over 50 and in younger women, and 30 times that in younger men. It is recommended that the Wolf-Schindler gastroscope be used routinely for gastroscopy in elderly women and in all outpatients. An appreciable number of accidents occurred with both the blunt metal and the rubber fingertips; it could not be determined which was safer. Since the introduction of penicillin a significant proportion of patients with esophageal perforations have recovered on medical treatment. Conservative treatment should be tried in mild cases, but when a gross leak is apparent or there is perforation of the lower esophagus immediate suture should be performed. Perforation of the stomach has been rare following the abandonment of the rubber sponge tip; when it occurs it may be treated medically. Six reactions to the anesthetic were reported, five of which were fatal. Of the deaths, four were atributable to overdosage. Four cubic centimeters of 2% tetracaine (pontocaine®) hydrochloride should be the maximum used as a local surface anesthetic. Owing to the definite risk attached to gastroscopy the indication for each examination should be clearly defined.

Influence of Androgens on Sexuality in Women.—Ten women between 37 and 63 with advanced metastases from cancer of the breast were treated with massive doses of testosterone propionate in oil. The doses varied between 200 and 300 mg. daily for several weeks until improvement occurred or the patient was obviously not benefited and was deteriorating rapidly. In those in whom clinical improvement was observed, the doses were gradually reduced in amount and frequency. An abnormal increase in sexual desire was recorded in those patients who had shown temporary clinical improvement. These observations confirm those of other workers on the effect of androgens on sexual behavior in female patients and are in accord with the experiments of Klein on animals. It is suggested that sexual behavior in women may normally depend more on suprarenal androgens than on estrogens.

- *Influence of Injections of Testosterone on Primary Chronic Polyarthritis. K. W. Kuipers.—p. 611.
- Combined Surgical and Injection Therapy in Varicose Saphenous Vein: Experiences in 556 Cases. J. S. van Coevorden.—p. 619.

Injections of Testosterone in Polyarthritis.—Kuipers points out that the earlier trials with hormone therapy in arthritis may be regarded as forms of steroid therapy. He mentions among others his report with Touw in 1938 on the use of progestin in primary chronic polyarthritis. He briefly discusses the use of pituitary adrenocorticotropic hormone and of desoxycorticosterone acetate together with vitamin C. This report concerns chiefly the results obtained with testosterone propionate. All the 20 patients treated with this hormone were men who had typical chronic polyarthritis with changes in the joints, muscular atrophies, "glossy skin," subfebrile temperatures, poor general condition, and increased erythrocyte sedimentation rate. The average duration of symptoms was three years and the patients had been subjected to other therapeutic measures before this treatment was begun. Testosterone propionate in oil was injected into the gluteal muscle in doses of 75 or 100 mg. twice each week. Patients showing no effects after six to eight injections were sometimes given doses of 200 to 250 mg., but after two such doses the usual 100 mg. doses were resumed. Doses were reduced to one a week in those showing improvement. This treatment proved effective in 10 of the 20 patients. The author feels that further trials with this treatment are justified.

- Tuberculous Pleurisy and Pulmonary Tuberculosis. B. van Vliet.—p. 684.
- *Peptic Ulcers in Aged Persons. J. ten Kate.—p. 689.

Hemorrhagic Diathesis as Symptom of Carcinoma.—In two women, 51 and 49, respectively, signs of hemorrhagic diathesis appeared, with thrombopenia as the most significant hematological change. Both patients died, one about six weeks and the other about two months after the first appearance of the cutaneous hemorrhages. Necropsies disclosed carcinoma of the ovary in one and of the stomach in the other woman. In both cases the carcinoma had metastasized into the bone marrow. There had been no other signs of carcinoma, before the hemorrhagic diathesis appeared.

Peptic Ulcers in Aged Persons.—On the basis of case histories of seven patients, who ranged in age between 73 and 79, the clinical aspect of peptic ulcer in aged persons are discussed. These patients did not have a long history of ulcer symptoms, the duration in the reported cases ranging from a few days to four months. In four of these patients hemorrhages occurred, and in one perforation resulted. Vascular sclerosis is probably an important factor in this type of peptic ulcer. The short duration of symptoms and the roentgenologic aspects often suggest carcinoma. When carcinoma is suspected or when hemorrhages occur, surgical treatment is advisable. Five of the seven patients here discussed were subjected to resection; in one a gastroenterostomy was done, and in one the perforation was closed. All recovered.

PAS and Streptomycin in Surgical Treatment of Pulmonary Tuberculosis.—Birath and his associates state that their comparative analysis in 1948 of the value of paraaminosalicylic acid and streptomycin respectively in connection with surgical treatment of pulmonary tuberculosis testifies to the importance of more consistent chemotherapy. Chemotherapy permits surgical treatment in patients not previously operable. In 1949 preoperative treatment with paraaminosalicylic acid was given to 73 patients, streptomycin to 12 patients, and combined paraaminosalicylic acid and streptomycin to 25. Many advanced cases were included. Surgical treatment was performed as planned in 107 cases, and after four months there are residual cavities in eight patients and spread in three. During operative and postoperative treatment the number of patients who received combined paraaminosalicylic acid and streptomycin was increased to 50. Systematic preoperative treatment starting, as a rule, with paraaminosalicylic acid is recommended. Streptomycin should be reserved for use when the effect of paraaminosalicylic acid is not fully satisfactory or for complications following operation, when it should be given in combination with paraaminosalicylic acid.

Symptoms of Toxoplasmosis.—Recent investigations show infection with Toxoplasma to be much commoner than was formerly supposed. When toxoplasmosis occurs in pregnancy, the infection may be transmitted to the fetus. The earlier in pregnancy the infection occurs, the greater seems to be the danger of fetal death and abortion; if the infection occurs during the later part of pregnancy the infant is born prematurely or at term, but with more or less grave symptoms. The most important symptoms in congenital toxoplasmosis are hydrocephalus, cerebral calcification, chorioretinitis, convulsions, and retarded mental development. Toxoplasma changes can be demonstrated in almost all organs. In typical congenital toxoplasmosis all the cardinal symptoms may be present or one or more may be lacking. Even in typical cases, however, decisive diagnosis must depend on the results of laboratory examinations. There is a form of congenital encephaloretinitis that suggests congenital toxoplasmosis but has a different and unknown etiology. The prognosis varies greatly. Postnatally acquired toxoplasmosis is due to infection in childhood or later and has no effects comparable to the extensive destruction in the central nervous system and eyes found in congenital toxoplasmosis. The author reports eight serologically established cases of postnatal toxoplasmosis, one case in a girl, 9, with peripheral lymphadenitis and signs of encephalitis and seven cases in adults, two infected in a Toxoplasma laboratory and five with spontaneous infections. The onset was acute, with fever, in five cases. The peripheral lymph nodes were involved in six cases. In two cases there was a purely glandular form of clinically manifest toxoplasmosis; this form seems to represent a transition to the subclinical form of the disease. Two patients with symptoms resembling those described by Pinkerton and Henderson were severely ill and had not fully recovered six months after the onset. In one instance with unilateral choroiditis as the only clinically demonstrable symptom the dye test (Sabin-Feldman) titer was 1:2,000 and there was complement fixation in a dilution of 1: 120. Treatment of three cases with aureomycin and one with sulfamerazine ("sulfadimine") had no certain effect.

Pathological Anatomy of Toxoplasmosis.—Necropsy in six serologically verified cases of congenital toxoplasmosis revealed an inflammatory process in the organs of the body, but without exception the most pronounced tissue changes were in the central nervous system. It was concluded that the infection spreads by hematogenous way and that the tissue of the central nervous system is especially susceptible. The grave character and wide extent of the changes in stillborn infants or infants who died at birth point to fetal transmission of the infection. In all cases the mother's blood gave positive serum reactions with high titer values. Biopsy specimens from the lymph nodes in four cases of acquired toxoplasmosis with acute fever and pronounced serologic reactions to Toxoplasma showed rather pronounced inflammation, characterized by swelling of the reticular cells and agglomeration of eosinophilic leukocytes and plasma cells in the tissue. In patients with fever from undetermined cause this pattern might suggest toxoplasmosis.

Laboratory Diagnosis and Epidemiology of Toxoplasmosis.—Congenital toxoplasmosis is commoner than previously supposed. Congenital toxoplasmosis seems always to have clinical manifestations; acquired toxoplasmosis usually seems to be asymptomatic. In congenital toxoplasmosis demonstration of the parasites in the tissue is comparatively easy; they can be demonstrated in great numbers in the cerebrospinal fluid. As blocking of the aqueduct by necrotic masses may prevent escape of the parasites into the lumbar fluid, ventricular puncture is advised. The parasites are identified by inoculation in mice and immunologic analysis of the strain isolated. Serologic tests should be performed in all cases of toxoplasmosis. The method of choice is the dye test according to Sabin and Feldman, in combination with complement fixation. In congenital toxoplasmosis the appearance of complement-fixing antibodies seems to be delayed, while in acquired toxoplasmosis the two reactions run a parallel course. In acute cases the dye test titer usually rises to values of 1: 1,000 or more; decrease is as a rule seen after three to six months. Persistence of high titers indicates the presence of an active focus. For diagnostic purposes repeated examinations are recommended. The toxoplasmin skin test might be useful in epidemiologic surveys. Performance of this test in Stockholm showed a high percentage of positive reactions. The incidence increased from the age of 5 to the age of 20, after which it remained about constant. Preliminary investigations of similar kind in northern Sweden showed a far lower percentage of positive results in adults. The uneven distribution of latent toxoplasmosis indicates an extrahuman reservoir of infection. Evidence points to insect transmission as a mode of spread.

Koch's Bacillus and Streptomycin.—In vitro experiments were performed with cultures of Mycobacterium tuberculosis obtained on microscopic slides. The technique made it possible to keep the cultures for a certain time in a medium to which dihydrostreptomycin had been added, then to wash them, to place them in a new test tube with a medium to which dihydrostreptomycin had not been added, and to repeat this procedure at any desired rate. Thus the effect of intermittent contact of M. tuberculosis with dihydrostreptomycin could be studied. Results showed that dihydrostreptomycin continued to inhibit the reproduction of the bacilli after the two were no longer in contact and that the period of inhibition increased with the concentration of the dihydrostreptomycin. At therapeutic concentrations and with bacilli of normal sensitivity, inhibition of bacterial growth was obtained in Youman's medium with a single eight hour contact every second or even every third day. Tubercle bacilli were immersed for several hours in a solution of dihydrostreptomycin of known titer. The bacilli then were removed by centrifugation, and the dihydrostreptomycin solution was again titrated. The significantly reduced titer proved that the antibiotic had been absorbed by the bacilli. This fixation of the antibiotic by the bacilli may explain the persistence of the inhibitory effect of the antibiotic, even if the medium may have become favorable to reproduction. It is essential to remember that the strains of bacilli used were highly sensitive to the drug, that the results varied with the culture medium employed, that the inhibition of the development of the bacilli is only one of the elements of the cure of a tuberculous focus, and that the destruction of the bacilli must be carried out by the organism as a function of the action of the leukocytes, which varies according to local anatomic conditions. The in vitro test must thus be interpreted with caution, but the authors believe that the results obtained may be of therapeutic significance at least in certain human cases.

- *Tuberculous Abscesses and Empyema Following Penicillin Therapy. G. Arce and J. Villota.—p. 1.
- *Psychic Incontinence of Feces (Encopresis). R. M. Calzada.—p. 15.
- *Pseudo-Orchitis in Children. F. J. Fernández.—p. 45.

Tuberculous Abscesses and Empyema Following Penicillin Therapy.—Arce and Villota report 13 cases of tuberculous abscess following intramuscular injections of penicillin and four cases of tuberculous empyema following intrapleural administration of penicillin in therapy of pneumococcic purulent pleurisy. The tuberculin test gave negative results before the development of the tuberculous disease and became positive after it in almost all cases. The clinical course of the disease was typical of primary infection in all patients. Many were infants who had not been exposed to infection, and some had been under constant medical care. The fact that these cases appeared in different clinics and in far distanct locales is evidence that such abscesses were not due to accidental contamination through technical defects at the time of the injection. The authors conclude that the etiological role of penicillin in the production of tuberculous abscesses and tuberculous empyema cannot be doubted in the cases they report. They emphasize the necessity for bacteriologic examination and guinea pig inoculation of the pus of all apparently sterile abscesses that appear in the course of penicillin treatment and of the pus from patients with purulent pleurisy that seem to be aggravated by penicillin therapy.

Psychic Incontinence of Feces (Encopresis).—Six children with psychic incontinence of the feces (encopresis) are reported on. The disease is evident in preschool and school-age children. It is most frequent among neuropaths who come from homes in which the moral, economic, and educative conditions are not favorable. Pathogenically, two mechanisms for the production of encopresis are accepted: (1) an increase in the rapidity and intensity of the defecation reflex, making voluntary control difficult, and (2) a decrease or lack of cerebral inhibition. A third factor is also evident in some cases, namely, hypotonia of the anal sphincter. The author concludes that the prognosis in encopresis is favorable. In the aforementioned cases, the treatment, which consisted of psychotherapy, produced good results in all cases.

Psuedo-Orchitis in Children.—Fernández discusses pseudo-orchitis in children and describes eight cases. The main causal factors of the syndrome are (1) torsion of the spermatic cord, (2) torsion of the sessile hydatid of Morgagni, and (3) the idiopathic hemorrhagic infarct of the testicle. Although the symptoms correspond distinctively to the variety of the anatomic component involved, the differentiation of some forms from others is difficult. The author establishes two phases in the differential diagnosis. In the first phase pseudo-orchitis is differentiated from acute infections, allergic, chronic, tuberculous, and syphilitic orchitis, whereas in the second phase the disease is differentiated from (1) pyogenic nonspecific, tuberculous, acute syphilitic, and chronic epididymitis and (2) epididymis and testicular tumors, local inflammation, and other local diseases. The treatment consists of early surgical detorsion of the testicle and orchiopexy of the testicle to the vaginal tunica of the testicle.

- *Single-Course Treatment of Syphilis. L. Prunes, M. Weinstein and H. Hevia.—p. 1.

Penicillin Implantation in Syphilis.—Results of subcutaneous implantation of procaine penicillin in 63 patients with syphilis are reported. Sixty adult patients each received 2,000,000 units of procaine penicillin (in a simultaneous implantation of two troches of 1,000,000 units apiece). The three remaining patients (children) had a single implantation of 1,000,000 units. In all cases spirochetes disappeared from the lesions within the first 24 hours and the syphilitic lesions healed or disappeared within one or two weeks after penicillin implantation. Ten of the 11 patients with seronegative primary syphilis maintained negative serum reactions during the entire observation period, seven of them for more than seven months. One showed a transitory positive serologic reaction that subsided within one month. All of nine patients with seropositive primary syphilis were controlled during an observation period of more than six months. Fifteen of 17 patients with secondary syphilis maintained negative serum reactions for more than four months. The fourth group of syphilitics who underwent procaine penicillin therapy included two adults with latent syphilis and five children with prenatal syphilis. Control of the disease was effected in all these cases following therapy without recurrences up to the present (more than nine months). The results of this study, on the basis of the 40 patients observed for more than four months, are satisfactory in all the cases of primary syphilis, in 82.7% of the secondary syphilis, and in 80% of the prenatal syphilis cases. Thus, 92.5% of all these patients responded favorably to procaine penicillin implantation therapy.

Subacute Bacterial Endocarditis.—Ten patients between 14 and 54 with subacute bacterial endocarditis were treated with massive doses of penicillin alone or combined with streptomycin for prolonged periods. Injections of water soluble crystalline penicillin were given every three hours. The daily dose varied from 320,000 to 2,000,000 units according to the clinical course. Treatment lasted seven weeks to five and a half months. Two patients received only 320,000 units of penicillin daily but had no recurrence for 20 and 22 months respectively after treatment was discontinued. To shorten the course of the disease, treatment was started with a daily dose of 1,000,000 units in the three patients who have been recently treated. One of the 10 patients, in whom there was complete resistance to penicillin, died from cerebral embolism after seven weeks of treatment. The remaining nine patients recovered. Seven were followed for 10 to 22 months after discontinuation of the antibiotics. There were no recurrences. One patient had temporary cardiac decompensation, and another had a cerebral embolism with hemiplegia within four and a half months after *treatment was terminated* but made a nearly complete recovery. Combined treatment with penicillin and streptomycin (0.6 gm. to 1.2 gm. daily) was given to five patients. Combined treatment with a daily dose of 1,000,000 units of penicillin and 1.2 gm. of streptomycin daily proved superior to treatment with a daily dose of 2,000,000 units of penicillin alone in one patient in whom a penicillin-sensitive but streptomycin-resistant strain of alpha-hemolytic streptococcus was demonstrated. Today combined treatment is the method of choice in resistant cases. It seems to have a bactericidal effect, while aureomycin and chloramphenicol (chloromycetin®) may have only a bacteriostatic effect similar to that of the sulfonamide compounds. Evidence of diffuse or circumscribed myocardial lesions was supplied by electrocardiograms in all 10 patients. Resistant infection and cardiac decompensation are the two main causes for the relatively unfavorable prognosis in subacute bacterial endocarditis. The follow-up period has been relatively short in the author's patients, and exacerbation of the defect of the cardiac valves and of the condition of the myocardium is likely. Early diagnosis seems to be decisive with respect to prognosis, although that has not been definitely proved because of the great variations of the disease.

•Infantile Hemiplegia and Its Treatment by Hemispherectomy. R. A. Krynauw.—p. 1091.

Hemispherectomy in Infantile Hemiplegia.—Hemispherectomy, not including the thalamus and the caudate nucleus and its tail, was performed in 14 patients between the ages of 7½ months and 21 years with infantile hemiplegia. There was one postoperative death, and treatment failed in another patient because of postoperative infection due to the formation of an abscess in the remaining basal portion. Results were highly satisfactory in 12 patients. Ten of these 12 patients had focal or generalized epileptic seizures before the operation, but none of them had attacks postoperatively. The pronounced disturbances of behavior and personality in all the patients were improved to a greater extent than had been expected. This improvement depends on the integrity of the remaining hemisphere and on its capacity for normal *function as soon as it has been freed from the abnormal* influence of the pathological side. The improvement of tonus and of function with return of motor power and diminished spasticity and clumsiness was significant. Reactions to pinpricks were good in all regions of the body, and articular sensations were restored at least in two patients. The preservation of the caudate nucleus is necessary for the restoration of the motor activity, while the putamen of the lentiform nucleus and the globus pallidus should be removed. The author believes that less radical neurosurgery, consisting of local excisions and incisions may occasionally prevent the recurrence of convulsive attacks, but the mental condition of the patient generally will not be benefited. Epilepsy and/or mental disturbances are to be considered as indications for hemispherectomy in patients with infantile hemiplegia.

•Cerebral Pneumatotherapy with Pure Oxygen: Technique, Indications, Biologic Syndrome, Results. P. Abély, P. Borenstein and J. Puech. —p. 1145.

Cerebral Pneumatotherapy with Pure Oxygen.—Cerebral pneumatotherapy with pure oxygen instead of air was practiced in a large number of psychiatric cases in the course of three years. By lumbar puncture 40 to 60 cc. of oxygen was injected into the subarachnoid space in two stages. The amount of oxygen injected equalled the amount of the cerebrospinal fluid removed. The pressure of the cerebrospinal fluid after the second injection was always significantly higher than at the beginning of the intervention. A terminal overpressure is indispensable for satisfactory results. The indications for pneumatotherapy with pure oxygen are the same as for that with air, but the biologic changes obtained within two hours of the intervention differed with the two techniques. Constant hypoglycemia, particularly pronounced in the first hour, was observed after the injection of oxygen in contrast to hyperglycemia after the injection of air. While red blood cell counts showed no changes after the injection of air, there was a definite increase in red blood corpuscles three to five hours after the injection of oxygen, and there was in addition neutrophil hyperleukocytosis at the fifth hour after the injection. The serum calcium level was significantly increased in only two patients, who were spasmophilic. Mild but constant hypoglycorrhachia was observed after the injection of oxygen. Examination of vaginal smears revealed shortening of the menstrual cycle and a rapid increase in acidophil estrogenic cells. Pneumatotherapy proved to be most effective when practiced in the preovulation period. Cerebral pneumatotherapy is to be considered a more satisfactory and less painful method with pure oxygen than that with air. It is suggested that the oxygen exerts an effect on the diencephalon by restoring simultaneously the whole equilibrium in some psychiatric cases. The oxygen injections may be repeated at three week intervals for more lasting results. Pneumatotherapy with oxygen is particularly advised in postpartum psychoses, since constant and permanent results were obtained in about 100 such cases.

•Observations on Use of Corticosterone and Ascorbic Acid in the Cure of Arthropathies. G. Tassinari and L. Rindi.—p. 561.
•Therapy of Brucellosis. M. Bassi and S. Menci.—p. 566.

Corticosterone and Ascorbic Acid in Arthropathies.—Tassinari and Rindi administered desoxycorticosterone acetate and ascorbic acid in treatment of arthropathies of different origin and nature in 15 patients of either sex between the ages of 25 and 74. The disease was severe and of several years' duration in all cases. One intramuscular injection of 5 mg. of desoxycorticosterone acetate in oil was given daily, followed immediately by an intravenous injection of a solution containing 1 gm. of ascorbic acid. The injections were given for a period that varied between 10 and 20 consecutive days, except to two patients who wished to discontinue treatment after three and five injections respectively, because of intolerance to it. The effects on pain and muscular function were spectacular but transient in four cases, mediocre and transient in four patients, and nil in seven patients. These drugs resembled cortisone in the clinical effects of the treatment and the lowering of the erythrocyte sedimentation rate several days after administration. The necessary doses, as given to the aforementioned patients, produced toxic symptoms, mainly hypertension with acute headaches, dizziness, in some cases acute or mild pruritus all over the body, and cardiac or renal symptoms in patients with cardiac or renal disease. The toxic symptoms subsided after discontinuation of the treatment. The authors therefore conclude that a definite cure was obtained in no case, but that the aforementioned treatment is of value in arthropathies of recent onset. The treatment is contraindicated for patients with hypertension, arteriosclerosis, or cardiac or renal diseases.

Therapy of Brucellosis.—Bassi and Menci administered one or more modern types of treatment to several groups of patients with acute brucellosis. The authors conclude that chloramphenicol and its synthetic derivatives are of the same therapeutic value as aureomycin in brucellosis. Antibrucellar vaccines, after chloramphenicol therapy, diminish the necessary quantity of the antibiotic and cause a permanent immune reaction. The *administration of neoarsphenamine* followed by administration of antibrucellar vaccines is indicated in very acute cases and when chloramphenicol cannot be obtained. The combined treatments of sulfadiazine, streptomycin, and quinacrine dihydrochloride (atabrine®) or of sulfadiazine, streptomycin, and penicillin provide a rapid and definite cure in cases particularly resistant to usual therapy.

Prophylactic Streptomycin in Thoracoplasty Operations.—A controlled study of the effect of routine streptomycin administration at the time of thoracoplasty is described. Two comparable groups of patients were observed. One group of 325 patients (the S group) received 1 gm. of streptomycin daily for two days before and 21 days after each operation or stage. The local application of 1 gm. to the wound at the time of operation was optional. Another group of 287 patients (the control or C group) received no streptomycin locally or intramuscularly before or after operation unless they were considered to have a tuberculous lung "spread" or a tuberculous wound infection. In the event of any complications, patients from either group were given 1 gm. of streptomycin daily for eight weeks or for four months, if necessary. The incidence of contralateral spread did not differ significantly between the two groups, but there was a significantly greater number of homolateral spreads in the controls than in the S cases. There was no significant difference between the groups in the incidence of transient or persistent atelectasis after operation. The incidence of serious wound infections was significantly greater in the controls. Sputum examination three months after operation did not show any statistically significant difference between the S and C groups. The total deaths, up to six months after operation, included six in the S group and eight in the C group. In the control group 11.6% of the men but only 4.0% of the women had homolateral spread postoperatively, whereas 8.7% of the men and only 2.4% of the women had operation wounds unhealed after three months. The routine use of streptomycin prophylactically in thoracoplasty operations is not advocated. The drug is best reserved for treatment of complications.

Tuberculosis and Pneumonoconiosis in Coal Miners.—A study of the development and progression of tuberculous shadows in the roentgenograms of coal miners is reported. In all, there were 1,514 pairs of roentgenograms. In 139 pairs the first showed a tuberculous shadow of clinical significance, and these 139 were used for the study of the progression rate. The remaining 1,375 pairs were used for study of the attack rate of tuberculosis, which, in the reinfection type of tuberculosis, was found to be related to the severity of the associated simple pneumonoconiosis. It is apparently reduced in cases of complicated pneumonoconiosis. The progression rate of tuberculosis in the presence of simple pneumonoconiosis is apparently slow. The prevalence of tuberculosis appeared to be higher among miners with simple pneumonoconiosis than in the general population. This high prevalence is related to the higher attack rate and lower progression and mortality rates from tuberculosis in miners compared with the normal population. Progressive massive fibrosis, characteristic of complicated pneumonoconiosis, may in itself be a modified form of tuberculosis occurring in a lung already affected by simple pneumonoconiosis.

Combination Resection-Injection Treatment of Varicose Veins.—Birch-Jensen says that varices are chiefly treated in four ways: conservatively, surgically, by injection, and by combined surgery and injection. Combined resection and injection has been used at Aarhus Municipal Hospital since 1947. Follow-up examination was made in 129 cases, in 75 men and 54 women, operated on from 1947 to 1949. In most cases the disorder had been present from 15 to 20 yr. There was at least nine months' observation time. Completely satisfactory objective results were seen in 66% of the cases and more or less pronounced recurrence in 34%. Subjective results were better than objective ones.

•Acquired Toxoplasmosis: Seven Cases of Strongly Positive Toxoplasma Reactions. J. J. C. Siim.—p. 353.

Demonstration of Tubercle Bacilli in Stomach Resection. K. Iversen and W. Kiaer.—p. 358.

Acquired Toxoplasmosis.—Seven cases of acquired toxoplasmosis, all with strongly positive Toxoplasma reaction, are reported. The main symptom was a pronounced pathological swelling of the lymph glands. In three patients universal adenitis was the only symptom, in three there were fever and uncharacteristic catarrhal symptoms, and in one pronounced fatigue. There was no exanthem, and the Wassermann and Paul-Bunnell reactions were negative. The glandular swelling lasted several months, and in three cases convalescence was characterized by much fatigue. No changes in the central nervous system and eyes such as dominate the picture in congenital toxoplasmosis were observed. Acquired toxoplasmosis may run its course as an inapparent infection. The author considers it likely that in the future positive Toxoplasma reactions will be found in at least some of the cases clinically diagnosed as mononucleosis. The natural mode of infection is not known, but the possibility of transmission through the alimentary canal as well as by insects must be considered.

Diagnosis of Congenital Cardiac Defects Suitable for Surgical Intervention. E. Mannheimer.—p. 129.

•Cerebral Lobectomy. K. Huber.—p. 134.

Immediate Satisfactory Results of Extirpation of Larynx for Carcinoma. O. Novotny.—p. 135.

Cerebral Lobectomy.—Lobectomy was performed on 13 patients, three men and 10 women between the ages of 20 and 50, of whom five had an oligodendroglioma and eight an astrocytoma. The frontal lobe was excised in 10 instances and the occipital lobe in three. Three patients died soon after the operation, but residual tumors were not demonstrated on necropsy. These patients died from acute anemia; preserved blood was not yet available for transfusion at the time of the operation. Four other patients died in one to seven years after the intervention. Necropsy was performed in two of them, and it revealed recurrences of the tumors. Two other patients were followed for three years and were free of complaints. The last four of the 13 patients answered a questionnaire. One operated on 12 yr. ago still had epileptic attacks and was blind, but already was so at the time of operation; two operated on one and six years ago had occasional attacks, but their working capacity was partially restored. The last remaining patient, operated on eight years ago, recovered completely and is able to do agricultural work. Homonymous hemianopsia occurred after the excision of the occipital lobe in two patients, but the patients were not much disturbed by it. An insignficant decrease in function occurred after frontal lobectomy in two other patients. The indications for lobectomy were justified in these 13 patients except for the two with recurrences. In spite of careful microscopic examination of the tumor in the course of the intervention, recurrences cannot always be avoided, because the extension of the tumor may not be visible macroscopically and it may not be possible to establish the presence of multiple tumors. The author believes that only frontal or occipital lobectomy is indicated and that either should be performed only for astrocytoma and oligodendroglioma. Diagnosis based on ventriculography should not alone be decisive for performance of lobectomy; the general condition of the patient must also be considered, and the definite decision should be made only after exposure of the brain. Lobectomy should not be performed as palliative treatment, since the result that may be expected will not justify the magnitude of the intervention.

Eclampsia Induced by Neurovegetative Disturbance of Circulation. H. Knaus.—p. 257.
*Treatment of Gonorrheal Vulvovaginitis with Penicillin. H. Peer.—p. 261.

Penicillin in Gonorrheal Vulvovaginitis.—Twelve female infants with gonorrheal vulvovaginitis were treated with penicillin. Fifty thousand units of the antibiotic were injected every three hours, with a total dose of 500,000 units. Local treatment was not given. The author advises against hormone therapy as an unphysiological procedure in the infant. Untoward reactions to penicillin were not observed. All the infants made a complete recovery. They remained in the hospital for an average period of one month. Cultures and microscopic follow-up studies were done for six months. Despite the unfavorable reports by other workers, penicillin therapy is considered the method of choice for gonorrheal vulvovaginitis in infants, provided that the adequate total dose of 500,000 units is administered. Combined treatment with estrogens or sulfonamide compounds is not necessary.

*Clinical Picture and Therapy of Endocarditis Lenta with Particular Consideration of Treatment with Streptomycin and Massive Doses of Penicillin. H. Kleinfelder.—p. 53.

Treatment of Endocarditis Lenta.—Forty patients, 37 men and three women, between the ages of 20 and 40, with endocarditis lenta are reported on. Nineteen patients had a defect of the cardiac valves that preceded the endocarditis lenta. The clinical picture of the disease was highly characteristic, with the organic heart defect detected by auscultation, enlargement of the spleen, focal nephritis, extremely increased blood sedimentation rate, temperatures ranging from subfebrile to fever, and clubbed fingers. Since January, 1948, 32 of the 40 patients had been treated with antibiotics. Seven patients were treated with 500,000 units of penicillin daily for 28 days, according to Christie's schedule, but a cure was not obtained in any of these patients, although the daily dose was increased to 800,000 units, with a total dose of 30 million units. Recovery resulted in seven of 11 patients who received massive doses of penicillin up to 6,000,000 units per day for eight weeks. Only temporary improvement had been obtained previously with smaller doses of penicillin in these patients. Twenty patients were given daily doses of 1 to 2 gm. of streptomycin, up to a total dose of 90 gm. Four patients recovered, and another was expected to. Four of these patients had responded only partially or not at all to previous treatment with penicillin. Streptomycin should be given a therapeutic trial in every case in which the symptoms of infection may not be satisfactorily improved by appropriate doses of penicillin. Since January, 1949, 12 of 21 patients who were treated with massive doses of penicillin and to whom streptomycin was given as an adjunct have definitely recovered. Recovery was expected in another patient. It should be emphasized that these highly satisfactory results were obtained in 62% of patients who had been ill for more than six months before treatment was instituted. Experience showed that prognosis of endocarditis lenta is unfavorable in patients with aortic insufficiency and pronounced hemodynamic manifestations; the occurrence of cardiovascular decompensation must be expected in the majority of these cases. The prognosis is more favorable in patients with a pure mitral effect, stenosis of the aorta, or aortic insufficiency not associated with hemodynamic manifestations.

*Prophylaxis and Therapy of Thromboembolism and of Postthrombotic Disturbances. H. A. Thies.—p. 164.
Study of Metabolism in Patients After Gastrectomy. K. Kremer.—p. 178.
Pyocyaneus-Meningitis After Lumbar Puncture. H. Reitter.—p. 181.

Prophylaxis and Therapy of Thromboembolism.—Of 1,229 patients who underwent major surgical intervention at the university surgical clinic in Hamburg in 1950, 40 (3.3%) had a postoperative thrombosis and six (0.5%) had a pulmonary embolism. One of these six patients died before medicinal treatment could be instituted. Postoperative prophylaxis of thrombosis with bishydroxycoumarin (dicumarol®) was given only to adipose and cachectic patients, to those with varicose veins, and to those with a history of previous thrombosis. Bishydroxycoumarin treatment was instituted on the third to fourth postoperative day with a dose of 200 mg. daily for the first two days. Subsequent doses depended on the prothrombin time, which was determined daily and maintained as nearly as possible between 20 and 40% of normal. In addition, 400 mg. of pure rutin was given daily for the protection of the vascular wall. Hemorrhages did not occur during this prophylaxis. So that the process of wound-healing would not be interfered with, heparin was not administered during the first 24 to 48 hr. necessary for bishydroxycoumarin to become effective. Not a single instance of thrombosis or embolism was observed during this prophylactic treatment, but the number of patients so treated was too small for definite evaluation of bishydroxycoumarin prophylaxis. Treatment of thrombosis or thrombophlebitis with bishydroxycoumarin was combined for the first three days with moist dressings and raising of the extremity, since heparin was not available. Hypoprothrombinemia of at least 20% and even less was the goal as long as symptoms of thrombosis were still manifest. Moist dressings were discontinued as soon as a prothrombin time of 30% was obtained; when it oscillated around 15% (usually after five days) the patient was allowed to move the extremity at will. Pain and tension usually disappeared within four to six days, and the duration of the thrombosis was shortened to eight to 15 days. Mild, short embolic attacks occurred in only 10 patients but did not necessitate special measures. Daily determination of prothrombin time, immediate institution of bishydroxycoumarin, and sufficient hypoprothrombinemia are indispensable for cure. The author's results as well as those reported in world literature showed that the anticoagulants are superior to any other drug used for prophylaxis or treatment. Although the anticoagulants were not always effective, the incidence of thrombosis, its duration, and the incidence of fatal embolism were much reduced. Severe hemorrhage may occur in about 2% of the cases, but death may be prevented nearly always with transfusions of fresh or preserved blood with sufficiently high prothrombin content. Heparin and bishydroxycoumarin do not clear up postthrombotic disturbances.

BOOK REVIEWS

Fundamentals of Clinical Fluoroscopy with Essentials of Roentgen Interpretation. By Charles B. Storch, M.D., Adjunct, Radiodiagnostic Department and Radiotherapy Department, Beth-El Hospital, Brooklyn, New York. Cloth. $6.75. Pp. 196, with 217 illustrations. Grune & Stratton, Inc., 381 Fourth Ave., New York 16, 1951.

To an old radiologist trained in the Holzknecht (Vienna) and the Levy-Dorn (Berlin) early schools of roentgenology, there is a nostalgic and comforting thrill to this author's attempt to arouse or revive an interest in fluoroscopy. The technological triumphs of modern radiography would seem to eclipse the fundamental and clinical satisfactions inherent in fluoroscopy. Of course it is essential that plenty of clinical experience enter into the interpretation of the fluoroscopic images, and it is also important to observe the demands for protection of both patient and fluoroscopist. As the author states, the literature of fluoroscopy is scarce and scattered. It is a neglected waif of radiology. The author also admits a Socratic adherence to logic and answerableness that is commendable. The author does not presume that fluoroscopy is a competitor to roentgen films. Rather fluoroscopy amplifies and frequently serves to avoid an unusual number of films for the patient in whom the movement or pressure displacement of viscera needs to be surveyed. The thoracic cage becomes an alluring and resourceful field for fluoroscopy, with its shift of fluid level, the diaphragmatic excursion, and the mediastinal variations by position. Abdominal emergencies of various types of gas retention from several causes can be studied without the inevitable delays of radiography. Now that amplification of fluoroscopic images with substantial gains in visual acuity and increased brightness of the screen images is available, there is every reason for one to believe that this revival of fluoroscopic interest is more than justifiable. Fluoroscopy must and will emerge from this tunnel of darkness in which it has been for decades. But there must be full understanding and observance of the demands of protection and the necessity of familiarity with normal and abnormal fluoroscopic anatomy and physiology, in addition to a full measure of clinical comprehension. Radiologists of this generation have had little experience with fluoroscopy compared to the first generation of continental radiologists who were trained with glass plates without even screens to intensify images. It is going to be interesting to witness this revival of simple fluoroscopy. This good book can show the way.

Therapie der Nerven- und Geisteskrankheiten. Herausgegeben von Wolfgang Holzer, Professor Dr.med. et Dr.Ing., Vorstand der psychiatrisch-neurologischen Universitätsklinik in Graz. Unter Mitarbeit von Hans Eichhorn, et al. Redigiert von Ernst Pichler. Cloth. Pp. 407, with 28 illustrations. Wilhelm Maudrich, Spitalgasse 1B, Wien IX/2, 1951.

The editor, Dr. Holzer, restricts himself to a general medicophilosophical introduction and relegates the main task to his associates. This treatise covers all types of therapeutic procedures, such as pharmacotherapy, physical therapy, therapeutic operations on the central and peripheral nervous system, specific therapy in diseases of the brain and meninges, treatment of neurosyphilis, and other diseases of the spinal cord, peripheral nerves and neuromuscular system. There are chapters on diagnostic procedures, shock treatments, convulsive disorders, psychotherapy, therapeutic use of hormones, vitamins, diets, and therapy of acute injuries to the central nervous system.

This monograph contains little that is of value to the practicing neurologist or psychiatrist. It is filled with therapeutic suggestions that have been gleaned from the literature of the past century and put together without critical evaluation. Most of the recommended forms of therapy are obsolete; to mention a few striking examples, leeches in cerebral hemorrhage, mercury and bismuth in central nervous system syphilis, morphine in postconcussion delirium, convalescent serum in epidemic encephalitis, and malarial fever treatment of acute anterior poliomyelitis. On the other hand, established methods of treatments which have been in use for a number of years are omitted or barely considered; for example, penicillin in neurosyphilis, the surgical procedures in cerebral aneurysms, and the value of the newer antibiotics. Many disease entities are not considered. The importance of the electroencephalogram in diagnosis and control of treatment of epilepsy is overlooked, and topectomy, transorbital lobotomy, and electronarcosis in the treatment of mental disorders are not mentioned.

These are but few examples of the defects of this monograph. It gives the impression of a book written in haste, by authors who have had little practical experience and who do not have the critical judgment which is needed in writing on subjects of therapy. Some of the defects may be excused on the basis that progress in medical science has been retarded in Austria by the war. This does not, however, excuse the lack of order in the presentation of the material and the failure of the authors to use discrimination in the selection of methods of therapy.

The printing of the book is good, but the binding is weak and easily broken. There are 28 illustrations, most of which pertain to the technic of lumbar and cisternal puncture and do not add to the value of the book. There is an inadequate bibliography at the end of each chapter. Practically all the references are to the German literature. References to the foreign literature cited in the text are not included in the bibliography. There is an adequate index.

Therapies in all fields of medicine are changing rapidly. The authors have not kept apace with the advances in the field of neurology and psychiatry. Their monograph is not, therefore, of any value to the student or to the specialist.

Roentgenologic Diagnosis of Diseases of Bones. By David G. Pugh, Assistant Professor of Radiology, Mayo Foundation, Graduate School, University of Minnesota, Minneapolis. [Reprinted from Nelson's loose-leaf Diagnostic Roentgenology.] Cloth. $6. Pp. 316, with 307 illustrations. Thos. Nelson & Sons, 19 E. 47th St., New York 17; Parkside Works, Dalkeith Road, Edinburgh 9, 1950; 1951.

This book is the section with the same title in Nelson's looseleaf "Diagnostic Roentgenology," edited by Dr. Ross Golden, Chief of the Department of Radiology at the Columbia Medical Center at New York City. This original section was written by Paul Hodges, Phemister, and Brunschwig. Pugh has retained much of the original section, which he acknowledges, and has added much, especially on the endocrinal, vitaminic, rheumatoid, neurologic, hematologic, and orthopedic categories of bone disease. Fractures are not discussed as such, but fractures as complications of systemic bone disease receive good attention. The dystrophies of bones receive elaborate attention, as do also bone tumors. There used to be about four bone diseases, to wit: tuberculosis, osteomyelitis, syphilis, and cancer. When improved sanitation methods for cattle and milk were adopted, the virtual elimination of tuberculosis followed. The sulfonamides have about eliminated osteomyelitis. Penicillin has conquered syphilis, and now the problem of malignancy is about to be solved. But a new array of bone diseases have arisen to baffle diagnostic skills. Pugh's book provides the avenues of analytical roentgen diagnosis. No longer does the orthopedist alone treat bone disease and trauma. Now the endocrinologist, the rheumatic and cardiac specialist, the neurologist, and others are appropriating treatment of bone diseases, each into his own specialty. But a book like this will help any and every specialist. Perhaps general practitioners might and could appropriate this whole field of the newer diseases of bone, saving the radiologist as the court of last resort.

Pugh's book is worthy of the author and his background. If Pugh has missed any of the new expressions of bone disease, it is just because they have not as yet been discovered. When bigger and better bone diseases are provided, Pugh can add appropriate postscripts.

The reviews here published have been prepared by competent authorities and do not represent the opinions of any official bodies unless specifically stated.

QUERIES AND MINOR NOTES

TRANSMISSION OF RABIES

To the Editor:—*1. Can a flea biting a rabid animal transmit rabies? 2. Can chickens contract the disease from a rabid animal? If so, can the fowl transmit the disease to an animal or human? 3. If a pregnant rabid dog is delivered by cesarian section and the mother animal has no contact with the litter, can the puppies develop rabies? If the veterinarian punctured his hand with the knife or needle during the operation, would he contract rabies? 4. I have been informed by a veterinarian that the virus has been recovered in the urine or milk of a rabid animal or cow. Is that correct? 5. If a dog is immunized against rabies can that animal become a carrier of the virus and infect a person by biting or can he transfer the virus to an unprotected animal?*

Bernard Greenberg, M.D., Brooklyn.

Answer.—1. No, rabies is not transmissible by fleas or any other arthropods. 2. (*a*) Yes, domestic fowl may contract rabies, although they are not so susceptible as mammals. (*b*) No instance is known in which rabies was transmitted by rabid chickens. 3. (*a*) This is a rather hypothetical situation, with which there is little or no practical experience. Natural transplacental transmission following natural infection in dogs has not been recorded. However, Konradi (*Zentralbl. Bakt.* 42 [pt. 1]:203, 1908) observed that rabies could be transmitted by pregnant dogs, following experimental infection, to the fetus and offspring. Other workers have failed to confirm this transplacental passage of the virus. (*b*) This is extremely unlikely in the light of present knowledge. Accidental contamination of the surgeon's or pathologist's wound would be more likely from contact with pancreas, kidney, or mammary glands, since the virus may sometimes be present in these tissues. 4. (*a*) Yes, rabies virus has been recovered from the urine or milk of rabid animals. (*b*) Infection from the handling of infected milk or urine is a very improbable mode of transmission. The danger of such occurrence would depend on the entry of the infected fluid into a substantially severe and fresh wound and also on the concentration of the virus in the contaminating fluid. Ingestion of infected cow's milk is a highly unlikely mode of transmission. 5. No, if a dog is immunized and fully protected, remaining refractory to infection, he will not be capable of transmitting the virus. In dogs there is no evidence of symptomless carriers of rabies whether immunized or not.

TOXICITY OF TITANIUM

To the Editor:—*I would like information on titanium poisoning.* *J. B. Havron, M.D., South Pittsburg, Tenn.*

Answer.—Titanium long has been accepted as without known toxicity. Its commonest form, titanium dioxide, is utilized in high tonnage in paint manufacture under conditions of gross exposure without known injury to workmen. Smaller quantities are introduced into cosmetics and skin medicaments without complaint of undesirable qualities. The term "titanosis" appears in the literature, and here and there cases have been reported in which pulmonary lesions have been attributed to titanium. Usually the onus may be traced to admixed materials such as silica. What has been noted in the case of titanium dioxide is not always true for some other compounds. Various salts may be detrimental, not because of the presence of titanium, but on account of associated radicals. Thus, titanium tetrachloride and titanium potassium fluoride may serve as examples of toxic agents in the action of which titanium itself is unfairly held responsible.

TREATMENT OF GASTRIC CRISES

To the Editor:—*A 51 year old man has had six severe attacks of gastric crises of tabes within the past year. A diagnosis of tabes was made in 1942, and he was given two years' treatment with arsenicals and bismuth. In 1945, he began to have gastric crises and was given 12,000,000 units of penicillin. Fever therapy was given but could not be tolerated. Beginning in August 1950, I gave him 250 mg. of aureomycin four times daily for three weeks. He has had two attacks of gastric crises since then. Five blood tests between 1946 and 1948 showed positive Kolmer (430000 to 444000) and Kahn (012 to 013) reactions. In May 1947 colloidal gold was 1221110000-0 and 12 mononuclear cells were found in the spinal fluid. At present the blood Kahn, Kolmer and Kline reactions are negative. Your opinion as to further treatment would be appreciated.*

Edward C. Halley, M.D., Fresno, Calif.

This inquiry was referred to two authorities, whose respective replies follow.—Ed.

Answer.—Some of these patients seem to progress despite all treatment, but others can be helped by a combination of specific and nonspecific measures. This patient has apparently had adequate amounts of specific therapy, but because of the elevated cell count in 1947 the spinal fluid should be reexamined for evidence of relapse or resistance. If there is any abnormality in cell count, protein, colloidal gold curve or spinal fluid Wassermann reaction, it might be of value to give another course of penicillin (9,000,000 units over a period of three weeks) followed by a reexamination of the spinal fluid in six months. Some syphilologists also give courses of 10 weekly injections of bismuth (bismuth subsalicylate in oil, 1.5 cc. intramuscularly) alternating with two month rest periods as long as the spinal fluid remains positive.

Nonspecific therapy may be of even greater importance. Marked symptomatic improvement often results from the following measures used in combination for many months: large doses of vitamin B complex, daily ultraviolet rays to the entire body, weekly autohemic injections for 10 weeks, elimination of coincidental infection, avoidance of exertion and insistence on adequate sleep with barbiturate sedation if necessary. Morphine should not be used for the recurrent gastric crises. Many patients thus treated die of the effects of addiction rather than from their disease. In the place of morphine, 3.0 Gm. each of chloral hydrate and sodium bromide in 30 cc. of water should be given per rectum and retained. This can be repeated every four hours as needed. Combinations of acetylsalicylic acid, phenacetin and sodium bromide may also be given by mouth for pain. Epinephrine, 0.5 cc. intramuscularly, sometimes stops an attack. Intravenous administration of dextrose and sodium chloride solution is essential if vomiting is severe.

Answer.—Gastric crises in tabes dorsalis are rarely benefited either by metal chemotherapy, penicillin, or any other form of drug therapy. There is perhaps a 25 per cent chance of complete relief and a 50 per cent chance of marked amelioration (in decrease of frequency and severity of attacks) if the patient can be properly treated with fever by means of induced tertian malaria. Whether this can be accomplished depends in part on his physical status and in part on the expertness of medical and nursing care during the malaria. If malarial therapy is without avail (and it should certainly be tried, if possible, before anything else), there remain only two possible recourses. The first of these is control of the attacks by means of morphine or a derivative, which obviously incurs the grave risk of addiction. The second is one of the several neurosurgical procedures that have been utilized with more or less success in the treatment of this condition. The most satisfactory of these operations is probably cordotomy, or combined sympathectomy and vagotomy.

The answers here published have been prepared by competent authorities. They do not, however, represent the opinions of any official bodies unless specifically stated in the reply. Anonymous communications and queries on postal cards cannot be answered. Every letter must contain the writer's name and address, but these will be omitted on request.

DENTIFRICE CONTAINING FLUORIDE

To the Editor:—*Is there any evidence on the desirability of using aqueous sodium fluoride solution brushed on the teeth daily? What strength would be considered most suitable?*

A. McQ. Thomson, M.D.,
Middle Park, Victoria, Australia.

Answer.—The results of a clinical study (Bibby, in "Dental Caries-Mechanism and Present Control Technics," St. Louis, C. V. Mosby Company, 1948, p. 151) in which children used a liquid dentifrice containing sodium fluoride do not support this suggestion. No reduction in dental caries was observed at the end of one and two years.

Indiscriminate distribution of even a 0.5% solution of sodium fluoride may not be free of hazards. The possibility that death of an adult human might result from the absorption of as little as 105 mg. of fluorine has been indicated (Gettler and Ellerbrook: Toxicology of Fluorides, *A. J. M. Sc.*, **197**:625 [May] 1939). This is the amount of fluorine in 50 cc. of a 0.5% sodium fluoride solution. An LD_{50} of 50 mg. or more per kilogram of body weight may be a better estimate of the acute toxicity of sodium fluoride (McNally: Four Deaths Caused by Sodium Fluoride, *J. A. M. A.* **81**:811 [Sept. 8] 1923; Cox and Hodge: Toxicity of Fluorides in Relation to Their Use in Dentistry, *J. Am. Dent. A.* **40**:440 [April] 1950). Even this value shows the dangerous potentialities of 0.5% solutions if made accessible to children.

CANCER AND THE PITUITARY GLAND

To the Editor:—*Has research been done on a possible correlation of cancer and the anterior pituitary?*

M.D., New York.

Answer.—There are no definite data in the clinical literature that demonstrate a direct correlation between the function of the anterior pituitary and the development of cancer. Certain animal experiments suggest that anterior pituitary hormones may be involved in the development and growth of tumors. Administration of a purified pituitary growth hormone to rats by Moon and his colleagues resulted in the development of neoplasms in several different organs. Administration of other purified pituitary hormones to animals has not been reported to produce neoplasms. Hypophysectomy may alter the rate of growth of certain transplantable tumors in animals.

There is evidence in both man and animals that alteration of the endocrine balance, especially of the adrenal cortex and gonads, can influence the rate of growth of some neoplasms. Alteration of gonadal function in certain strains of animals has been demonstrated to result in the development of neoplasms. Since the endocrine function of the adrenal cortex and gonads is regulated by tropic hormones from the anterior pituitary, it is reasonable to suppose that alterations in the function of the anterior pituitary might influence the development and growth of tumors. Quantitative methods for the determination of anterior pituitary function in man are not adequate to permit critical evaluation. Recent advances in the preparation of purified anterior pituitary hormones will afford an opportunity to determine the effects of these substances when administered to animals and man.

INOPERABLE LUNG CANCER

To the Editor:—*A patient with carcinoma originating in the apex of the left lung has been declared inoperable. Can you give me information as to whether aminopterin or amethopterin would be of benefit in this case?* *M.D., Louisiana.*

Answer.—Aminopterin and amethopterin are folic acid antagonists which are still decidedly in the experimental stage. Also, they are by no means free from toxic effects. There is no good evidence that they will be useful in the treatment of advanced cancer. The article by Schoenbach, Greenspan and Colsky entitled "Reversal of Aminopterin and Amethopterin Toxicity by Citrovorum Factor," which appeared in The Journal Dec. 30, 1950 (page 1558) elaborates on this subject.

HYDROGEN ION CONCENTRATION OF CEREBROSPINAL FLUID

To the Editor:—*1. What is the permanganate or organic index of cerebrospinal fluid? 2. What variation occurs in the hydrogen ion concentration of the cerebrospinal fluid in tuberculous meningitis?*

S. M. Epple, M.D., Cleveland.

Answer.—The permanganate or organic index is a figure expressive of the total amount of organic matter in the cerebrospinal fluid as measured by the reduction of a solution of potassium permanganate of known strength. The normal index for fluid withdrawn by lumbar puncture is 1.3 to 1.8, ventricular and cisternal fluids having indexes which are slightly lower, 1.1 to 1.5. A most marked increase occurs in organic disease of the meninges. High values are found in all disorders associated with increase in the cell and protein content of the fluid. Contamination of the fluid with blood invalidates the results of this test. In general the index parallels the cell and protein content of the fluid. The determination of the permanganate index adds little to the information gained from other, more specific, procedures. The hydrogen ion concentration of cerebrospinal fluid examined immediately after withdrawal is almost the same as that of the blood, the p_H varying normally from 7.4 to 7.6. Levinson has found that when the cerebrospinal fluid is allowed to stand, exposed to air, the alkalinity increases, because of the loss of carbon dioxide from the fluid. The alkaline reserve, as measured by the carbon dioxide-combining power, is also practically identical with that of blood plasma (55-75 volumes per cent).

The p_H of the fluid in tuberculous meningitis is usually within normal limits (7.4-7.6), the alkalinity increasing on standing, as in normal fluid. In the suppurative meningitis the fluid is slightly more acid (p_H 7.2-7.5), the increase being due, in all probability, to the presence of lactic acid. When the fluid is allowed to stand, the acidity shows much less tendency to decrease than in the case of normal fluids, actually increasing in some instances (Levinson). This is perhaps due either to an increased rate of glycolysis or fermentation, or to increased production of carbon dioxide by the cells present in the fluid, balancing the loss of carbon dioxide which occurs when the fluid stands exposed to air.

TREATMENT OF MONILIASIS VULVAE

To the Editor:—*I would appreciate information on the therapy of moniliasis vulvae. Aqueous gentian violet, 2 per cent, has been used as have iodine and vinegar douches. There is no evidence of diabetes mellitus.*

Julius N. Bell, M.D., Kewanee, Ill.

Answer.—It is assumed that by the treatment of moniliasis vulvae, also is meant vaginitis. If the lesion is only of the vulva, other conditions must be thought of, such as kraurosis, leukoplakia, carcinoma, benign warts and ring worm. If it is of the vagina also, use of methylrosaniline chloride (gentian violet) appears to be the treatment of choice. It can be administered several ways:

1. Scrub the vagina with a green soap (not tincture) and paint generously with 2 per cent aqueous methylrosaniline chloride. Repeat in five to seven days until all symptoms and signs are gone.
2. Use methylrosaniline chloride jelly individual dose applicators, inserted like a tampon and insert a tampon afterward, leaving it in for 24 hours. Repeat once a week until cured.
3. Use methylrosaniline chloride suppositories until cured; these when used daily are irritating. Combinations of the above are useful. Propionate compound jelly (propion gel®) has also been reported as helpful.

One should ascertain that a mixed infestation is not present. Trichomonas commonly occurs with yeast; this condition can be treated with diiodohydroxyquinoline or other appropriate remedies. Other lesions, such as cervical erosions, should also be treated. On occasion, overtreatment causes as much or more trouble as the original infestation. In this case, stopping all treatment and merely giving weak vinegar or lactic acid douches will bring relief.

PIGMENTATION FOLLOWING LACERATIONS

To the Editor:—*A patient received facial lacerations in an auto accident. While scars are well healed but irregular, they show deep pigmentation, which extends somewhat beyond the outline of the injury. They are very disfiguring. Please give information as to the permanency of this pigmentation.*

R. C. Hunt, M.D., Fairmont, Minn.

Answer.—Pigmentation of the skin and subcutaneous tissues may result from friction, pressure, heat, other physical and chemical agents, chronic infection, chronic inflammatory processes or wounds. The slightest trauma in dark-complexioned persons may produce an increase in pigmentation. Therefore, it is not unusual for deep pigmentation to form in and around the scars of wounds, especially if the wound took a long time in healing.

Increased pigmentation may be due to increased melanin (iron free pigment), hemosiderin (iron containing pigment) or deposits of foreign or extraneous materials. If foreign or extraneous materials have been tattooed in the wound areas the discoloration may be permanent and require surgery for removal. If the pigmentation is due to hemosiderin or increased melanin, many months may pass before the normal color of the skin returns. In some cases, when the pigmentation is due to increased melanin, it may remain indefinitely.

HIGH DIASTOLIC BLOOD PRESSURE

To the Editor:—*A 39 year old man has a blood pressure of 130/100, otherwise he is apparently healthy. He is 5 ft. 10 in. tall, weighs 195 lb., is a nondrinker and smokes 20-25 cigarets a day. What treatment will lower the diastolic pressure? What may be the significance of the low pulse pressure?*

Daniel Rosenfeld, M.D., Rockville Centre, N. Y.

Answer.—In the first place, it is important that one ascertain that the blood pressure readings are correct. The auscultatory method of blood pressure determination is sometimes open to error because of the occurrence of an auscultatory gap; for example, with aortic stenosis or hypertension or both, there may be an area of auscultatory silence of 20 or 30 mm. above what is erroneously considered the systolic pressure. It is possible that the systolic reading may be 180 with silence from 160 to 120 or 130 with the diastolic reading at 100 or 90. It is even possible that an auscultatory gap may come with relatively low pressure with systolic at 130 and diastolic at 70 and a gap between 100 and 80. A small pulse pressure otherwise suggests aortic stenosis, pericardial constriction, slight diastolic hypertension, which may occur early in the development of essential hypertension (hyperpiesia), or even coronary insufficiency, such as may be found in a few patients at the beginning of their illness with angina pectoris. A relatively high diastolic pressure without systolic hypertension has been seen also in rare cases of coarctation of the aorta. Follow-up studies of this case may prove to be of considerable interest and importance.

URETHRAL PAPILLOMAS

To the Editor:—*Can podophyllin be safely used in the treatment of recurrent urethral papillomas? Can it be instilled directly, thereby bathing normal mucosa as well as pathological mucosa without injuring the former? If not, can it be applied directly to involved areas by endoscope? What percentage and what vehicle is best for such a condition?*

Murray Russell, M.D., Beverly Hills, Calif.

Answer.—Podophyllin (25 per cent) in oil solution or in ointment is effective in removal of urethral papillomas, especially condyloma acuminatum. Although podophyllin has been used along all portions of the urethra and even in the bladder, its use should probably be restricted to warts that occur at or near the urethral meatus. Although it may not cause permanent damage to normal mucosa if washed off in several hours, it can cause severe local irritation and ulceration. In order to avoid subsequent stricture or to prevent overlooking early carcinoma, one should treat deep-seated warts by instrumental methods.

GENITAL TUBERCULOSIS

To the Editor:—*A married woman has had amenorrhea since the age of 17. Her first menstrual period was at age 13, and periods were regular for the next four years, after which she missed months at a time. Two years ago she underwent dilatation and curettage for possible determination of the etiology of her sterility, and a diagnosis of tuberculosis of the endometrium was made from the endometrial scrapings. Physical examination disclosed nothing essentially abnormal. X-rays of the lungs were normal. Results of tuberculin and sedimentation tests were negative. The patient's weight has been more or less stationary, and nutrition has been maintained. The only symptom suggestive of any disturbance has been night sweats, which have subsided with dihydrostreptomycin injections. Any information that you could give me concerning treatment would be appreciated.* *M.D., Rhode Island.*

Answer.—Since this seems to be a local infection in the genital organs (uterus and perhaps tubes), conservative treatment can be advised. First, it is recommended that cervical smears for acid-fast bacilli be made. At this date they may not be found, but a thorough search should be made nevertheless and an animal inoculated. The tuberculin test should be repeated. The reaction should be positive if the process is tuberculosis. Higher dilutions of tuberculin may be required to prove the presence of the tuberculous infection in this type of case.

The treatment with dihydrostreptomycin is entirely rational—about 1.5 Gm. a day for 60 to 90 days. Paraaminosalicylic acid may be given after the dihydrostreptomycin treatment or concurrently with it—about 1 Gm. per 10 pounds (4.5 Kg.) of body weight in four daily doses. It may be dissolved in water and given with fruit juices or other liquids. It is better to give it around meal time, because otherwise it causes irritability and nausea. The sodium salt is much better than the free acid. The free acid may be neutralized by addition of 0.6 Gm. of sodium bicarbonate per gram of drug.

If the symptoms are not controlled by treatment with the respective drugs, or if they recur after the treatment has been finished, surgery should be resorted to. The condition in so many of these cases is controlled and ultimately cured by drug therapy that surgery is rarely necessary.

EARLY CANCER OF CERVIX AND THE SCHILLER TEST

To the Editor:—*Please discuss the Schiller test (Gram's iodine) for early cancer of the uterine cervix.*

Joseph G. McKinnon, M.D., Hattiesburg, Miss.

Answer.—J. P. Greenhill (Office Gynecology, ed. 5, Chicago, Yearbook Publishers, 1949) presents the following data concerning the Schiller test. Kermauner and later Schiller proved that in carcinoma of the portio vaginalis, which constitutes about 96 per cent of the cancers of the cervix, there is such an early stage that it cannot be recognized with the naked eye. In this early stage there is no invasion of the underlying tissue; the only sign of malignancy is a change within the cells. It is well known that the stratified squamous epithelium of the vagina and the portio contains glycogen, provided it does not become keratinized. Lahm observed that this glycogen disappears suddenly when the squamous epithelium changes into carcinoma. Therefore, the proof of the presence or absence of glycogen may serve to distinguish normal from cancerous cells. Schiller discovered a means of detecting this in the living woman in a harmless way. He found that, if an aqueous solution of iodine is poured on the cervix, the normal stratified squamous epithelium of the cervix and vagina assumes a mahogany brown stain in about 30 seconds, whereas carcinomatous areas remain unstained and therefore are whitish. Hence, there is a sharp demarcation between the carcinomatous and the normal epithelium. The iodine solution which must be used is Gram's solution. Schiller advocated Lugol's solution for his test, but he referred to the Lugol solution used for bacterial staining. This is equivalent to our Gram solution, which consists of 1 part iodine, 2 parts potassium iodide and 300 parts water.

A speculum is introduced into the vagina and all mucus and discharge are removed from the cervix and upper part of the vagina. Then 20-30 cc. of Gram's solution is poured on the cervix and upper part of the vagina from a cup or other vessel having a long, sharply pointed tip. The solution is then spread around with a cotton applicator or a cotton pledget. After half a minute the excess of solution is gently absorbed with a pledget of dry cotton. The cervix is then examined carefully in good light. If it is mahogany brown all over, there is no carcinoma, because all the epithelium contains glycogen. If one or more white unstained areas are observed, there is only a suspicion of carcinoma, because not all white areas signify cancer. There are other conditions, benign ones, in which glycogen disappears from the epithelium. Glycogen is always absent in the presence of carcinoma but not only in its presence. In some instances white areas are observed because there is no squamous epithelium, as in the following conditions: (1) trauma, (2) leukoplakia, (3) keratinization developing in a prolapse, (4) hyperkeratosis of the squamous epithelium of the cervix, such as occurs in syphilis, (5) erosions of the cervix and (6) some nabothian follicle cysts superficially situated in the cervix.

Since all white areas are not carcinoma, the only way to determine whether cancer is present is to remove all white areas and have them examined microscopically. Because the carcinoma is limited to the surface cells and there is no invasion of the underlying tissue, all that is necessary is to scrape off the white area with a sharp curet or scalpel or to lift it off with a curet.

Schiller suggested that these pieces of tissue be fixed not in watery formaldehyde but in Carnoy's solution, which consists of 60 parts absolute alcohol, 30 parts chloroform and 10 parts glacial acetic acid.

This test is to be used only when the cervix appears normal to the naked eye, that is, when the squamous epithelium is intact. When an outspoken carcinoma is present with ulceration and destruction of tissue, this test is unnecessary and will fail to reveal the characteristic white areas. The Gram solution must be replenished frequently, because it is essential that it be fresh.

The Schiller test will not reveal an early carcinoma often. However, even if only one early cancer is detected among a few hundred women, detection by the test will probably mean the saving of that one woman's life.

CHRONIC PANCREATITIS

To the Editor:—*What is the present method of treatment of chronic pancreatitis?* *M.D., New York.*

Answer.—The treatment of chronic pancreatitis may be divided into two parts—that concerned with elimination of etiological factors and that directed to relief of symptoms.

1. When a diagnosis of chronic pancreatitis has been established, it is important that the functional state of the hepatobiliary system be determined by thorough laboratory and clinical investigation. In all cases in which chronic pancreatitis is accompanied by evidence of hepatobiliary disease, treatment should first be directed, medically and surgically, to the correction of these defects. When disease exists elsewhere in the gastrointestinal tract, this, likewise, must be corrected by appropriate measures.

2. When etiological factors have been corrected, the remaining treatment of pancreatitis is directed toward the correction of functional errors produced by elimination or reduction of pancreatic enzymes and hormones and, second, by measures directed to relieve the distressing symptoms of the disease. None of these measures will correct the underlying pancreatic abnormal condition. The diet should be high caloric with fat restriction, to reduce the steatorrhea. The amount of fat restriction depends on the degree of steatorrhea. In general, the patient should be able to tolerate from 50 to 100 Gm. of fat. It may be helpful, in addition, to administer bile salts by mouth at meal time to further minimize the symptoms due to a large amount of undigested neutral fats in the gastrointestinal tract. Other medications should be administered as follows: pancreatin in large doses, up to 15 Gm. daily divided equally between the three meals or, preferably, the triple strength pancreatin in correspondingly lesser doses; calcium to replace that lost in the feces, and supplementary vitamin B complex. If diabetes mellitus is present, it may be of a severe grade and may require large doses of insulin for control. Surgical intervention is indicated for cysts, abscesses, pancreatic calculi, obstruction to the pancreatic duct system and intractable pain. In the latter case, sympathectomy has been reported to be of some value. The inquirer is directed to a complete survey of this situation reported by Comfort, Gambill and Baggenstoss (*Gastroenterology 6:239 [April]; 6:376 [May] 1946*). The indications for surgical treatment of chronic pancreatitis are thoroughly discussed in this article.

TRICHIASIS

To the Editor:—*An elderly physician diagnosed trichiasis in his left eye in August 1949. A well known eye man removed two inverted lashes. A similar condition was treated at practically monthly intervals during the remainder of the year. In 1950 the patient was annoyed by inversion in one or both lids 14 times at intervals of three to 10 weeks. On April 25, 1950, in addition to plucking two lashes from the upper lid and three from the lower, the oculist removed a sac of calcium from the outer canthus of the same eye. Two lashes were removed from the lower lid, on December 27, and a similar sac in the same place was treated in April. Three eminent oculists say the condition is likely to continue indefinitely and that the etiology is not known. Can you give any advice?* *M.D., New Jersey.*

Answer.—Minor trichiasis is usually treated by electric epilation of the offending lashes. Where the condition is persistent and more widespread, "Ziegler" cautery punctures are done in the skin near the outer lid margin to promote ectropion from controlled scarring. Severer trichiasis, if due to entropion, is treated by a "skin-muscle" operation. The offending spastic marginal muscle is removed and the tarsal plate grooved, and the lid heals in good position. Recurrent calcium deposits in and under the conjunctiva require general treatment for calcinosis and local conjunctival treatment. The general treatment for calcinosis should include reduction in the use of vitamin D. Locally in the conjunctiva the calcium plaques are removed and a mild collyrium should be persistently used for conjunctivitis. Irrigations of upper and lower canaliculi should be done to insure freedom from a chronic infection, such as Streptothrix.

TINNITUS RESULTING FROM ACOUSTIC TRAUMA

To the Editor:—*A 60 year old man complains of tinnitus (left ear), following a gunshot explosion three years ago. He has been treated by ear specialists and neuropsychiatrists, with no improvement. I have tried foreign protein; histamine, diathermy, nicotinic acid, vitamin E, testosterone, diethylstilbestrol and calcium gluconate intravenously and iodides. Can you suggest anything else that might be tried?*

W. J. Hossley, M.D., Deming, N. Mex.

Answer.—Tinnitus can be relieved by therapy only when it is due to reversible ear pathology, such as occlusion of the eustachian tube, impacted cerumen, otitis media or otosclerosis (in which the fenestration operation frequently, but not always, improves the tinnitus). When tinnitus is a result of acoustic trauma following gunshot explosion, there is damage to the cochlea which is irreversible and therapy is of no value. The patient must be encouraged to learn to live with his subjective head noise. A mild nerve sedative may be of slight help.

MONGOLISM

To the Editor:—*A 3 month old mongoloid infant is the fifth child. The other four are normal. The mother, age 38, had a thyroidectomy for a large adenoma in 1947. Is there any relation between the thyroidectomy and the mongoloid child?*

G. A. Goshgarian, M.D., Round Lake, Ill.

Answer.—As far as can be determined, disease of the maternal thyroid gland plays no role in the etiology of mongolism in the offspring. It is rare for more than one mongoloid child to be born in a family. On the other hand, the condition has been observed in brothers and sisters a number of times. Mongolism may occur either early or late in the reproductive life of the mother. It occurs much more frequently at the latter time. There is no treatment for the condition.

THE SPECIALIST LOOKS AT EVERYDAY MEDICAL CARE IN INDUSTRY: ORTHOPEDICS

Harvey E. Billig Jr., M.D., Los Angeles

Industrial medicine has of recent years grown into a broad specialty, embracing the fields of preventive medicine, safety, and toxicology, as well as all the ordinary medical specialties.

Paralleling this growth have been three major developments with which industrial medicine has had to be integrated: The first has been the tremendous advance in medical knowledge; examples are the effects on both medical and surgical care of the discovery of the various antibacterial agents and of the metabolic action of the steroid-producing endocrine glands. The second development has been the change in labor-management policy brought on by the slowing of the tide of immigration from Europe, forcing the long-term employment of the mass of workers as ready replacements became unavailable. This stimulated closer study of industrial injuries in order to ascertain methods of prevention and care so as to conserve the labor force. Such studies gave rise to industrial accident commissions to adjudicate awards. The third development has been the trend toward pensions and care for both industrial and nonindustrial disability, bringing with it at the same time a tug of war among the various plans for provision of pensions and care: (*a*) industrial accident insurance company types with cost-plus premium, based on the average of costs of previous years; (*b*) self-insured types, aimed at reducing costs and protecting the worker; (*c*) Government types, involving social security; (*d*) union types, so far dealing chiefly with pension provisions. The scope of orthopedics in industry hence encompasses the care of the individual person from insemination to dissemination, including pregnancy as well as senility.

FIBROUS CONTRACTURE

There are many good books on fractures, dislocations, burns, tendon injuries, etc. However, a need also exists for practical knowledge of the bodily processes, involving, first, growth and development (anabolic dominance); second, intermediary processes, and then senility (catabolic dominance).

A study of the applied physiology of fibrous-tissue metabolism throughout life's cycle gives a remarkable view of the etiological basis and a key to the therapeutic correction of many of the common orthopedic complaints met with in industry.

A vast framework of fibrous connective tissue develops to furnish the ties that hold the body together. Areolar tissue lies beneath the skin; fibrous tissue sheathes each muscle fiber and muscle, nerve fiber and nerve, blood vessel, lymphatic, liver cell and lobe of the liver, and so on, ad infinitum. The sheathings take on denser proportions to assume the characteristics of fascia, to segregate and encapsulate the various structures of the body; of ligaments, to hold the joints together, and of special ligaments, to perform particular functions, such as the inguinal ligament, iliotibial band, and ligamenta flava.

Many examples of healing of localized injury show that, just as in wound healing, there is an increased production of fibrous tissue, which then contracts. In Volkmann's ischemic contracture the muscles become nearly completely replaced by fibrous contracture.

The tendency for fibrous tissue to contract, and hence constrict, is recognized as one of the fundamental properties of all protoplasm. This contracture may be a localized one, as in a wound healing; an areal one, as in Volkmann's ischemic contracture, a sprained joint, or a torn muscle; a multiarticular one, as in arthritis (steroid metabolism); a multiosseous one, as in osteitis fibrosa cystica (parathyroid origin). Even the simple process of an unaccustomed "hike" will result in sufficient irritation stimulus to the fibrous tissue to cause it to contract and produce a stiffness the next and following day. Athletes, dancers, gymnasts, and cats all know that they must counteract the stiffening by means of mobilization stretching, and that as the years go on the tendency to tighten up becomes greater, so that the boxer at 30 is no longer as agile as he once was.

Combating the fibrous capsular and ligamentous stiffness in joints, the consulting physician in physical medicine at St. Thomas' Hospital, London, Dr. James Mennell, has recently rewritten a two-volume book [1] on painless joint-mobilization manipulations covering the entire body.

Read before the Section on Preventive and Industrial Medicine and Public Health at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 28, 1950.

METABOLIC CHANGES

Many years ago, Dr. F. L. Hisaw started investigation of steroid metabolism, and in 1926 published his earlier studies of its effect upon relaxation of fibrous tissue (ligaments).[2] Now a host of workers throughout the world are studying the effects of the steroids on control of the fibrous (collagenous) tissue diseases, so that almost weekly are announced new discoveries that additional diseases are to be classified as such and are susceptible to steroid therapy.

A frequent complaint of industrial workers is that of persistent disability due to joint pain and swelling after an injury that, in many instances, should have been expected to clear up after only a brief interval. In examining these workers, it can be noted that a high percentage present the picture of vasomotor instability, with flushed ears and hands, low energy, labile low blood pressure, doughy consistency of muscles, tophi on the ears, and a record of some emotional imbalance. Adrenal cortex extract, if carefully given, will, over a period of four to six weeks, markedly reduce the disability, which is really a gouty diathesis based on a hypoadrenia and flared up in a joint by localized trauma. It has been noted that colchicine not only is an alkaloid but has the qualities of a steroid, and, if it is given by mouth to effective dosage (just short of producing nausea, intestinal cramps, or diarrhea), use of the other steroids can be discontinued after a time and the patient will stay balanced and free of symptoms.

High-Protein, Very Low-Carbohydrate Diet

May Have	
Vegetables	
Avocados	Broccoli
Cabbage	Brussels sprouts
Celery	Cauliflower
Cucumbers	Eggplant
Endive	Kale or collards
Lettuce	Leeks
Olives	Mushrooms
Radishes	Okra
Tomatoes	Rhubarb (no sugar)
Tomato juice	Sauerkraut
Water cress	Spinach
Artichoke	Squash
Asparagus	Swiss chard
String beans	Carrots
Beet greens	Onions
Beets	Rutabagas
Turnips	
Fruits	
Papaya	Muskmelon, cantaloupe, honeydew melon
Grapefruit	Strawberries
Grapefruit juice (no sugar)	Watermelon
Lemons	
Meats	
Bacon	Liver
Beef roast	Lean meat
Beefsteak	Pork chops
Beef	Sweetbread
Chicken	Turkey
Ham	Veal cutlets
Heart	Veal roast
Lamb	Fowl
Fish	
Bass	Sardines, canned
Codfish	Trout, brook, lake
Halibut, fresh	Tuna
Oysters, raw	Herring
Salmon, canned	
Nut meats	
Brazil nuts	Butternuts
Miscellaneous foods	
Broth	Ham
Cod liver oil	Lard
Cooking oil	Mineral or salad oil
Custard, no sugar	Soybean flour
Eggs	Cottonseed flour *

Avoid	
Vegetables	
Artichokes, Jerusalem	Corn
Lima beans	Potatoes
Parsnips	Succotash
Green peas	Beans, except soy
Chili sauce	Potato chips
Fruits	
Blackberries	Blueberries
Cranberries	Cherries
Gooseberries	Currants
Oranges	Grapes
Orange juice	Grape juice
Peaches	Huckleberries
Pears	Raspberries
Pineapple	Bananas
Apples	Plums
Apricots	Prunes
Dairy products	
Malted milk	
Cereals	
Cream of wheat®	Puffed rice
Corn flakes	Rice

Carbonated drinks	Macaroni
Chocolate	Spaghetti
Cocoa	Sugar, granulated
Ginger ale	Chewing gum
Honey	
Breads, cakes, pastries	
Bread	Cookies
Crackers	Pie
Cake	Pudding

* Flour available as Nutty-Brown® flour from Cedar Valley Mills, Cedar Valley, Texas.

Women during their cyclic steroid fluctuation at the different phases of the estrus cycle tend to present symptoms and signs of any imbalance. A premenstrual triad of fall in energy, crabbiness, and mental depression indicates estrogenic deficiency. A premenstrual period of increased tension, with sensitive breasts, indicates progesterone deficiency. The hypersensitive woman with a tendency to fatty padding, easy mental and physical bruising, constant complaints of pains in the back, neck, head, or "some place," and a premenstrual burst of energy (for example, meticulous cleaning of the house every month) is suffering from functional hyperinsulinism.[3] The dextrose tolerance curve will be particularly flattened during the premenstrual spurt-of-energy phase. A high-protein, very low-carbohydrate diet (Table) will correct the symptoms and lead to a gradual weight loss, even though as much is eaten as is desired of the "may have" diet list (including fats! unless otherwise contraindicated), provided rigid abstinence from the "avoid" list is maintained. Excess fat, if present, will be reduced. In some instances, there is at first very little actual weight change, although the patient's size decreases. This is explained by the fact that this diet instigates a positive nitrogen balance, and the fat loss is replaced by protein (muscle), which takes up less room per equivalent weight.

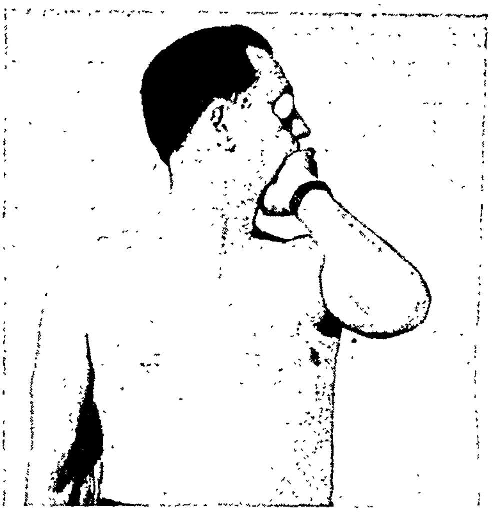

Fig. 1.—Forced craniocervical rotation.

USE OF MOBILIZATION TECHNIQUES

In the industrial field the biggest "headache" is the backache and its accompanying sensory-nerve peripheral pain and motor-nerve muscle spasm. The terms "railroad spine," "gold bricker," "neurotic," "compensationitis," "malingerer," and many others, have arisen to becloud the issue. Several diagnostic points have recently been recognized as showing that these backaches with their peripheral-nerve signs are of truly organic

3. Billig, H. E., Jr., and Spaulding, C. A., Jr.: Hyperinsulinism of Menses, Indust. Med. 16: 336-393 (July) 1947.

cause. 1. Frequently a restriction of motion of the spine in the region complained of, due to fibrous fascial ligamentous contracture, is found, accompanied with sensory pain and motor muscle spasm into the area of distribution of the peripheral nerves, the foramens of which are constricted where they pass through the constricted fascial ramifications. Careful history-taking frequently elicits the factor causing the contracture to be a strain while lifting, in which a few fascial fibers may be torn and the fibrous response to the insult is subsequent contracture. One hears many stories such as this: "I sprained my back yesterday, Doc, and seemed to get over it after a little while; but this morning, when I tried to get up, it was so stiff and sore, and the pain was so bad down my leg, that I had to roll out of bed." A generally unappreciated fact that is known to all concerned with peripheral-nerve surgery is that mechanical compression (e. g., squeezing with a hemostat) of a peripheral nerve causes a feeling of pain radiating into the peripheral distribution of its sensory nerve fibers, with muscle spasm in the peripheral distribution of its motor nerve fibers. If these "stiff" patients are tested by placing manipulative tension on the contracted fascial ligamentous bands, the foraminal nerve compression is additionally increased, and the peripheral-nerve signs of pain and muscle spasm are increased. 2. Electromyographic examination of the muscles reveals, in most cases, a multiple peripheral-nerve irritation and not a specific nerve-root irritation type of distribution pattern, indicating a peripheral-nerve irritative factor.

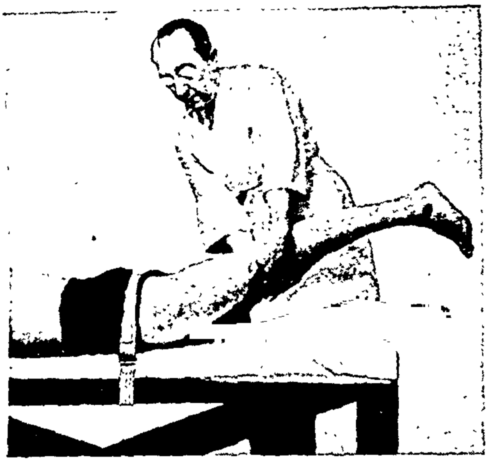

Fig. 2.—Exacerbation of symptoms by a pull on ligaments running from dorsolumbar portion of back to anterior pelvis and leg.

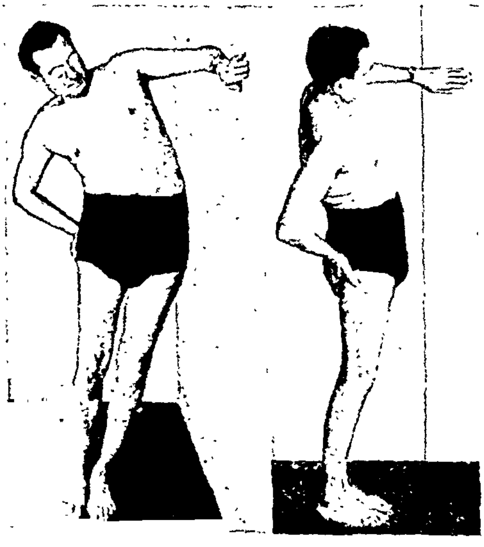

Fig. 3.—Loosening of contracture through forced posterior tilt of back and pelvis on the leg.

Chronic posture habit results in shortening of the fascial ligamentous fibrous structures to accommodate the posture maintained. When this is occupational, and when the occupational posture habit becomes the chronic posture habit, the gradually ensuing contractural stiffness results in not only a poor posture habit but symptoms [4] as well. The management of a telephone company noticed a huge prevalence of backache, dysmenorrhea, and occipitocervical headaches radiating to the temporal region among the thousands of girls seated with forward thrust of head and neck at switchboards. Examination revealed a contracture of the ligaments in the cervical region and in the lower back region, radiating to the anterior pelvis, thence to the leg and iliotibial-band attachment at the lateral condyle of the tibia. In these girls the forward thrust of head and neck and the forward-tilted pelvis had thus become a fixed posture habit. Placing an additional pull on the contracted ligaments in the neck by means of forced craniocervical rotation (Fig. 1) exacerbated the headache radiating up over the head into the peripheral distribution of the greater and lesser occipital nerves. After mobilization of this contracture by means of progressive accumulative loosening through forced cervical-rotation stretching exercises done routinely three times to each side three periods daily (Fig. 1), the headaches cleared up, not to return. Likewise, placing an additional pull on the ligaments running from the dorsolumbar portion of the back to the anterior pelvis, thence to the leg (Fig. 2), exacerbated the symptoms of backache and menstrual cramps (pain radiating into the peripheral distribution of the ilioinguinal and iliohypogastric nerves arising from the twelfth dorsal and first lumbar nerves passing through the contracted fascial ramifications). After mobilization

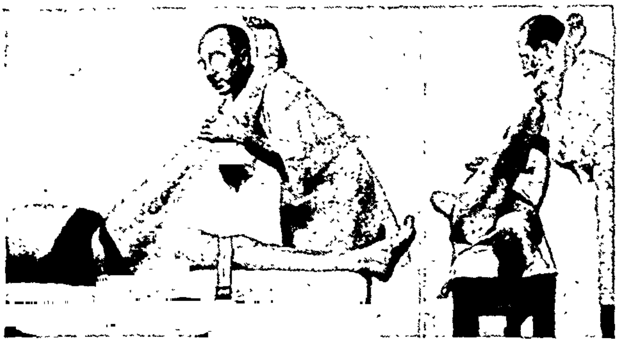

Fig. 4.—Exacerbation of symptoms through a pull on contracted ligaments, increasing compression stimulus to nerve.

of the contracture by means of the progressive accumulative loosening through forced posterior tilt of back and pelvis on the leg (Fig. 3) done routinely three times to each side three periods daily, the backache and menstrual cramps cleared up, not to return. These "stretching exercises" are now a part of the employee health service program of American Telephone and Telegraph Company and are illustrated by diagrams in a booklet distributed to all its employees. On the "work to win" program at Consolidated Vultee Aircraft Corporation during World War II, up to 40 days per hundred women per month were lost by absenteeism due to these complaints, in spite of a handsome bonus for the persons of each group each month, provided there was no off-duty among the group. During the first 10 months after instituting the mobilization-stretchings program (voluntary!) off-duty time was reduced to zero among these thousands of women.[5]

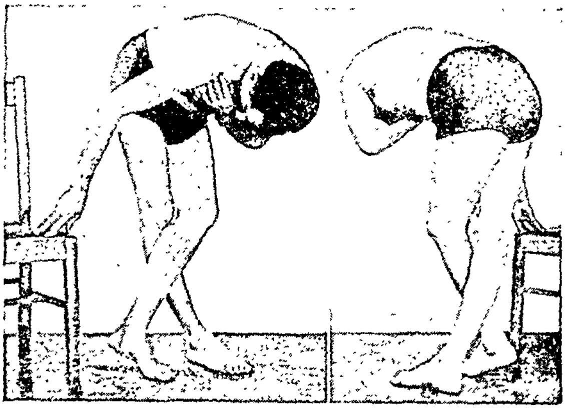

Fig. 5.—Correction of posteriorly tilted pelvis by means of stretching exercises.

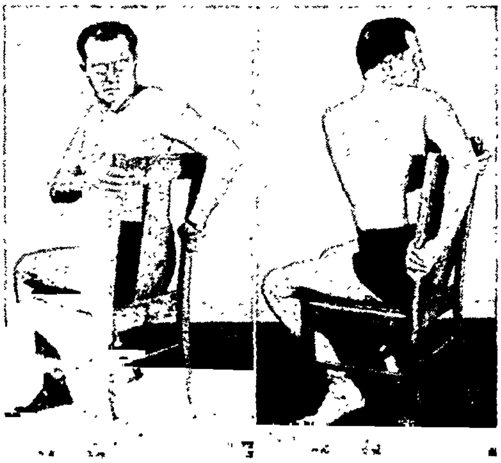

Fig. 6.—Forced trunk rotation.

In lathe workers it has been noticed that the assumption of a posteriorly tilted pelvis posture enables the employee to last out the day without tiring. Unfortunately, this leads to a chronic posture habit of posteriorly tilted pelvis, and hence flattening of the lumbar part of the spine. After a time the ligaments between the lower back and posterior pelvis, thence to the leg and iliotibial-band attachment at the lateral condyle of the tibia, contract, and the man can no longer execute a full forward bend. The contracture constricts the foramens through which pass the nerves making up the lumbosacral plexus and gives rise to complaints of backache and/or pain radiating into the peripheral distribution of the nerves so irritated. The nerves involved are commonly (1) various portions of the sciatic-nerve distribution as far as the peroneal or posterior tibial distribution in the foot[6] and (2) nerves radiating from the sacroiliac plexus through the hip anteriorly as a femoral-nerve distribution as far as the medial aspect of the knee and then "through the knee." Placing an additional pull on the contracted ligament (Fig. 4) causes increased compression stimulus to the nerve and exacerbates the symptoms complained of. Again, in this region, the fibrocytic contracture can be loosened by progressive accumulative mobilization by means of stretching exercises (Fig. 5) done routinely six times to each side three periods daily.

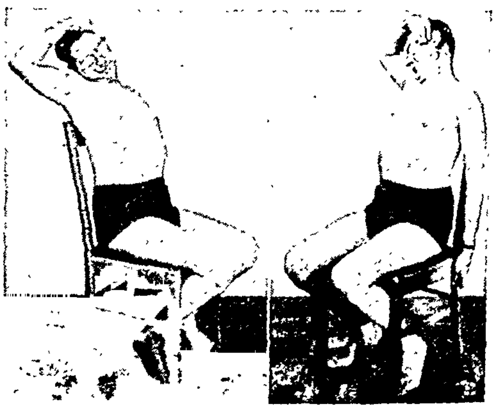

Fig. 7.—Mobilization stretching to relieve symptoms of intercostal neuritis.

In the dorsal area of the spine the complaint may be of a pain "between the shoulder blades," radiating to the anterior portion of the chest as an intercostal neuritis, and frequently felt only as an anterior chest pain. Testing is by means of a forced trunk rotation (Fig. 6). Treatment by mobilization stretchings (Fig. 7) done routinely three times to each side three times daily will bring relief.

Brachial-plexus irritations, giving rise to peripheral-nerve pains radiating out toward the shoulder and arm, can be exacerbated in testing by means of lateral tilt of the head and neck, keeping the chin well retracted and turned toward the direction of tilt (Fig. 7). Mobilization stretching is carried out by repeating the procedure routinely three times to each side three periods daily.

During the past few years these practical methods of combating the commonest complaints have been instituted in a number of industries and school systems.[7] It is always well to encourage the confidence of the employee, recognize and treat symptoms early, keep him on duty if possible, and see him frequently in order to keep up the morale until such time as he has progressively loosened the ligaments and mobilized sufficiently to begin to obtain relief.

It may, in severe cases, be necessary to give passive assistive mobilization stretchings[8] if the patient is not able to do them hard enough by himself to accomplish a progressive loosening.

In a major oil-tool manufacturing company backaches and sciatica were so prevalent that it was decided to institute a plant program of immediate mobilization stretchings in all cases in order to prevent contracture after back strains, and in order to mobilize whatever contracture was already present. A technician was trained at the Billig Clinic and then placed on duty at the plant to carry out the program immediately after the doctor's examination, the employee staying on duty. For several years following the start of this program, there was no lost time from these complaints, other than that necessary for the doctor's examinations. Recent check reveals that in that plant all the foremen have now been trained to recognize even mild complaints in the men of their group and to report them immediately to the medical office, so that mobilization treatment can be started before contracture has become severe.

SUMMARY

It is pointed out that increased medical knowledge, changing industrial employee-employer relations, and the trend to total industrial and nonindustrial care have had great influence on developing the important field of industrial medicine.

The importance of fibrous (collagenous) tissue contractures and their relation to production of the common industrial complaints of backache and peripheral-nerve pain, with ensuing loss of time, employee disability, and impaired work efficiency, are discussed.

Metabolic changes based on abnormalities of steroid endocrine balance producing many of the orthopedic complaints in industrial practice are briefly outlined.

Therapy by use of readily available steroid endocrine preparations is presented.

Mobilization techniques by means of progressive accumulative fascial ligamentous stretching to correct fibrous-tissue contractures and relieve backache and peripheral-nerve pain are briefly summarized.

THE SPECIALIST LOOKS AT EVERYDAY MEDICAL CARE IN INDUSTRY: PSYCHIATRY

Floyd O. Due, M.D., Oakland, Calif.

The psychiatric field has a large role to play in the department of industrial medicine. It cannot be overemphasized that many lost hours in terms of manpower could be saved by the consideration that employees are persons who react to even subtle stresses and tensions in the industrial facility as a whole, and that each employee brings to work the tensions of his own family relationship, as well as those from his own general social milieu. It has long been accepted that absenteeism, work slowdowns, and accident-proneness are influenced by such emotional tensions. The plant physician occupies a unique position between management and the worker. The position of the doctor in our culture allows for special confidence from the worker, even though the worker may consider that the doctor represents management. The doctor's attitudes can, therefore, be very influential with the worker, and if the doctor is to function to the best interest of the plant his attitudes should also be influential with the management. Thus, he can arbitrate many potential grievances that might lead to emotional tensions and breakdowns.

PSYCHIATRIC ORIENTATION

It is obvious that only the largest of industrial facilities can have a psychiatric specialist as part of the plant medical team. It then devolves on the full- or part-time physician and the members of the nursing staff to acquire a psychiatric orientation in which evidences of emotional tensions can be recognized. Although everyday treatment in the psychiatric field will not seem as concrete as the local treatment of minor injuries and illnesses, it can be seen that an awareness of emotional problems can lead to therapeutic actions that are concrete and valuable to the industrial facility.

It is unlikely that the plant medical staff will frequently be faced with extreme psychiatric emergencies requiring immediate attention. The chief emphasis, therefore, must be placed on prevention of disability from emotional disturbances and psychiatric illnesses that could arise from complications in the worker's industrial and personal life. Such an emphasis presumes that the medical staff be able to serve the whole industrial plant from the standpoint of elimination of job tensions, employer-employee relations, personnel placement with attention to consequent job satisfactions and dissatisfactions, counsel in instances of overt tension, and referrals to psychiatrists and psychiatric clinics when indicated.

Perhaps the greatest step toward the development of a psychiatric orientation in the medical staff is the cultivation of an alert awareness of the emotional attitudes and tensions in the everyday lives of the workers to whom care is administered. The physicians and the nurses of the staff should be encouraged to study psychiatric texts and articles in which this orientation is elaborated. They should be willing and able to listen to the patient with an ear toward the patient's emotional state as well as toward his physical state. In dealing with the patient, they should avoid a disciplinary, judgmental, and critical attitude. They should be able to produce in the patient the feeling that they are friendly and im-

---

Read before the Section on Preventive and Industrial Medicine and Public Health at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 28, 1950.

partial confidants who will at all times try to see the patient's side of the story. A failure in this relationship between the medical staff member and the worker will lead to the withholding of information that might be more important in the long run than the minor injuries or illness that presumably brought the patient to the medical department. The medical staff members should have enough authority to make recommendations regarding manipulation of the patient in his industrial setup.

FUNCTIONS OF MEDICAL STAFF

By far the most important part of the staff's function involves careful history taking with the permissive attitude previously suggested. While eliciting the history, there should always be an awareness of the emotional potentiality behind the complaints that are presented. Even if the patient's complaints do not seem valid or concrete, the interviewer should consider that every complaint represents some real problem for the complainant. It is, therefore, the physician's task to try to diagnose the latent problem, even though it might not turn out to be a specific problem of organic medicine. In utilizing this attitude, great care should be taken not to give the employee the impression that the awareness of emotional problems on the part of the medical staff members means that every patient is considered to be a potential "goldbricker." Such an attitude on the part of the medical personnel soon becomes well known by all the employees in the plant, and proper rapport for elaboration of emotional problems is, therefore, lost by all but a few employees. Eadie [1] called this phase of the history taking the search for the "latent complaint." He emphasized that all the following measures should be taken by the physician in tracing down such latent factors in the patient's complaints. He stated that the patient's story should be checked against physical findings; that the previous history should be correlated for facts that tie in with actual physical disease or with neurosis; that the nurse's observations of the patient should be checked; that the supervisor's observations should be checked, and that in some instances the physician should go into the shop personally and check the man's job and group situation. He also emphasized that the patient's home situation should at least be inquired into and that the response, or the lack of response, to treatment should be carefully observed and recorded. These measures would certainly represent the extent to which a medical team with psychiatric orientation could follow the rule that "every complaint represents some real problem for the complainant."

Careful records should be made of these historical investigations of the medical department. These records should be kept in close conjunction with the progressive records of the physical examinations and periodic health checks. Results of all special examinations and consultations should be a part of this record. The number of days of sickness and absenteeism should be correlated. It is extremely important that even minor accidents be recorded, along with the examiner's impression of the emotional attitudes of the injured patient. The patient's manner of relating his history and complaints, an evaluation of his facial expressions, and the amount of pressure apparent in his general speech and attitudes, should all be recorded as possible signs of emotional factors in the presenting complaints. Such carefully kept historical and medical records will pay large dividends on later investigations into the fields of potential psychiatric or emotional breakdowns. For instance, a succession of minor injuries might lead to the suspicion of an eventual depressive illness or perhaps even of a potential psychotic breakdown.

RECOGNITION OF POTENTIAL BREAKDOWNS

Some of the "signals" that might indicate potential breakdowns can be summarized: for instance, the restlessness, irritability, hyperactivity, and emotional instability of the hypomanic person, or the opposite trends, such as psychomotor retardation and the pessimistic and self-accusatory attitudes of the worker with potential depression. Preparanoid breaks may be signaled by increased complaintiveness against supervisors and fellow employees, as well as by more general ideas of reference and tendencies toward ideas of persecution. Preschizophrenic signals might involve withdrawal, flattening of emotional response, apparent preoccupation, automatic mannerisms, and strange or eccentric behavior. Neurotic and psychosomatic disabilities may be heralded by increased frequency of visits to the medical facility with physical complaints out of keeping with organic findings. In these persons physiologic evidences of anxiety and tension, along with the recording of the degree of insomnia, would be important.

Treatment that can be given by the industrial medical team short of referral to a specialist in psychiatry may include the process of catharsis, in which the physician or nurse is a permissive listener to the complaints and problems of the employee. Often such catharsis can afford sufficient release of tension to allow the patient to manage his own problem. Furthermore, it is possible that from the employee's release of personal feelings the physician or nurse can isolate some factors relative to which recommendations, reassurances, and suggestions can be given. Manipulation of the environment can also be accomplished, perhaps by correction of certain discomforts in the work situation, by arbitration of irritating occurrences among co-workers and between employees and supervisors, and by discussions with the foreman or executive in an attempt to eliminate the sources of tension. The physician also can make suggestions regarding the disturbances in the home situation, as, for instance, recommending that the worker's spouse go to a doctor or psychiatrist.

Sometimes the symptoms themselves afford clues to the exciting agent of the disturbance. For instance, recurrent headaches often are indicative of underlying resentment and hostility that cannot be expressed overtly. This resentment might be a part of the worker's family situation, but it can also be a result of his relations with other employees or his supervisors. For instance, the apparently unjustified promotion of a younger and newer worker might produce such a situation. Upper gastrointestinal complaints often are indications that the worker's sense of dependent security is threatened. Questions can be directed toward elaboration of this factor in both the home and the work situations. Diarrhea and colitis symptoms often occur in a setting where the victim has an excessive need to please his superiors, thereby sacrificing his own individuality. Symptoms referable to the opposite mode of lower bowel function, that of retention, i. e., constipation and its complications, often occur in those who have a great sense of being exploited by the work situation and who are on the defensive against such exploitation. Symptoms referable to the back often occur in workers who, on the one hand, have a strong sense of responsibility and, on the other, have an overwhelming feeling of inferiority in the face of responsibility. The above are all generalities that might aid in tracing down emotional sources of physical symptoms.

[1] Eadie, G. T.: Practical Methods for Handling Psychosomatic Problems in Industry, Indust. Med. 18: 369-371 (Sept.) 1949.

REFERRALS

If there is an apparent, serious psychiatric condition that cannot be managed by the medical staff, then the worker should be referred to a psychiatrist or to a mental health clinic. The patient should be carefully prepared for this referral from the beginning in order to prevent a hostile attitude that might make his visit to the psychiatrist unfruitful. Some general explanation of the mechanisms by which emotional problems can produce physical symptoms might reassure the patient that such a specific referral does not indicate that the medical staff considers that the worker is approaching some serious mental breakdown or insanity. In general, the patient should always be told that he is going to a psychiatrist rather than to a nerve specialist or neurologist. Such attempts to attenuate the situation usually lead to a handicap in the psychiatrist's relations with the patient for either diagnostic or therapeutic purposes. In cases of probable psychotic complications, it is well also to inform a responsible member of the patient's family of the situation and to have that person accompany the patient to the psychiatrist's office. This is important because the relative can give objective and factual information that the psychotic patient may not be able to verbalize, and he also can be responsible for initiating hospital and sanitarium care if necessary. It is well to prepare the psychiatrist with some general estimate of the patient's problem and to furnish him with a summary of the employee's previous work and health record.

SPECIAL PSYCHIATRIC PROBLEMS

It is considered that some attention should be given to special psychiatric problems that might confront the general medical staff at the plant. Chronic and recurrent acute alcoholism is one of the most important of these. The incidence of chronic alcoholism in the United States is high and seems to be increasing. Obviously, this disorder takes a great toll from industry from the standpoint of inefficiency on the job, absenteeism, and actual loss of and disability in workers who have been the recipients of a long and expensive training program. The last effect is particularly felt in the case of the "secondary" alcoholic who acquires the condition gradually after a relatively well-adjusted early life. Some of these persons can be helped by psychiatric treatment, if the condition is recognized and if they can be convinced that they should seek psychiatric help.

A special problem that engenders actual financial loss to the company directly, as well as indirectly through impaired morale of the co-workers, is the condition known as accident-proneness. Many investigators in the field have found that accidents are more likely to occur in a certain group of persons. In fact, nearly all the accidents in a plant might be attributed to a relatively small percentage of the personnel. Csillag and Hedri, in 1949,[2] delineated some of the factors in the history and examination of the persons in this small percentage. They stated that 54% of the patients in this group had lost one of their parents in childhood or did not even know their father or mother. Almost one-third of the accident-prone patients' deceased fathers had been the victims of violent death. There is a suggestion that accident-proneness in this series represented identification with the violent death of the father. Seventy per cent of the accident-prone patients could not give free expression to aggression. Several had tried to do this indirectly by choice of vocation or by their indulgence in certain sports; but where such efforts proved insufficient, and, where the moral standards were at a relatively high level, the patient tended to choose the accident solution to the problem. Thus, the patient turned his aggression against himself in the form of recurring accidents. These investigators also found that purposeful accidents could have as a motive the prevention of loved ones from leaving the victim. Accidents also occurred among competitors who were reckless with their own physical welfare in order to achieve more than others. These accident-prone persons can be isolated by history and by the record of minor injuries and, perhaps, given specific treatment to produce some insight into these morbid areas of their personality structure.

Another important special problem is that of industrial accidents in which a battle for compensation becomes an important factor. I have had occasion to examine many of these cases in which prolonged medical, orthopedic, and surgical measures had no therapeutic success. Psychiatric examination and history revealed that at the time of the accident nearly all these patients had some grievance that was not recognized on the original treatment of the injury. The administration of these cases aggravated, rather than minimized, the grievance. For instance, the practice of transfer of the responsibility for injured workers to a relatively unknown insurance company left the patients without any friendly person in authority to be the guiding and integrating factor in their treatment. Rather, the patients were sent to various doctors for consultations, and occasionally their conditions were given diagnoses that did not hold up under subsequent investigations. The patients' need for a concrete physical justification for their disability led to fixations on the area of mistaken diagnosis. It also led to resentments against those doctors who later did not agree with the previous mistaken diagnosis. As a result of being bandied about, the patients developed confusion and resentment that built up the original grievance to almost insurmountable heights. By the time these patients reached a psychiatrist, it was impossible to resolve the complicated superstructure of grievances and countergrievances without complete settlement of the case by cash payment. The cash payment represented at least some reward for the original grievance and for the subsequent grievances that piled up in the course of the patients' circuitous journeys through hospitals, doctors' offices, and courts. It must be honestly admitted that these patients occasionally suffered real indignities at the hands of some physicians who are poorly oriented in terms of a human approach to the patient. I have been placed on record, in testimony to a court, that poor management of this type in itself represents a source of injury to the patient and that it is, therefore, compensable. This stand was recognized as valid by the court in one outstanding case. I have come to the conclusion that many of the compensation cases that terminate in court battles have come to this end through continued episodes of mismanagement. I believe that a careful investigation of the emotional factors at the time the injury was sustained, along with sympathetic and understanding management early in the condition, would have forestalled many of these eventually expensive court proceedings.

---

[2] Csillag, and Hedri, E., Jr.: Personal Factors of Accident Proneness, Indust. Med. 18: 29-30 (Jan.) 1949.

Psychotherapy is extremely difficult after a case of this type has been complicated to the degree described above. By the time the patient sees a psychiatrist, his whole emotional set is to prove and maintain his illness at all cost, inasmuch as the relief of pain through psychiatric means would be tantamount to admitting that he was "faking" all along. It is also difficult to accomplish successful psychotherapy in a situation in which the court has granted a disability pension and has instructed the insurance company to pay for psychiatric treatment of the patient in question. My experience supports the views of others who have stated that an outright cash settlement, with the removal of the case from further court action, is the only measure that can release the patient from his need to maintain a stubborn stand against those whom he now feels have injured him in a variety of ways. In conclusion, I recommend that a closer liaison be kept by the plant physician or his representative with those patients whose treatment has somehow progressed into the hands of the insurance company and its doctors. Such a representative can obviously be closer to the employee and can be helpful in interpreting to the injured worker the significance of the various treatments and opinions that have been rendered.

THE SPECIALIST LOOKS AT EVERYDAY MEDICAL CARE IN INDUSTRY: CARDIOLOGY

B. M. Overholt, M.D., Knoxville, Tenn.

Interest in the subject of everyday medical care in industry from the standpoint of cardiology was accelerated by experiences during World War II, when it was necessary to employ manpower from the 4-F category. This increased the incidence in industry of hypertension, arteriosclerosis, rheumatic heart disease, psychosomatic disorders, and other cardiac defects. To a great extent experiences with these groups proved that persons who had cardiac disorders with a limited disability could carry on very well in industry.

Now that manpower is more plentiful, the limited cardiac cripple is again coming up against the barrier that has so long stood in his way, namely, the attitude of the employer that more or less insists that an employee be on a full-duty status, using Army terminology, and that there is very little place for an employee who can do limited duty only. Correction of this fallacy rests on education of management and union leaders, showing them statistically that the cardiac with a limited disability can be as productive as any other person, provided there is proper selective job placement.

A few statistical studies present evidence that persons with cardiac conditions are a good employable risk. Dr. Howard Rusk,[1] in a recent report, cited the latest of these studies which was made by the Bureau of Labor Statistics for the Veterans Administration. This study compared 1,800 workers having cardiac impairments with 3,000 unimpaired fellow workers on the same jobs. Although the persons with cardiac disease were slightly higher in absenteeism, disabling work injuries, and voluntary quit rates, differences were so slight that they were not considered significant. For example, the cardiac workers averaged two and one-half days a year more absenteeism than their unimpaired fellow workers but more than compensated for the time lost by their increased efficiency and stability.

The second problem in the management of the industrial cardiac worker resolves itself in the treatment and observation of those employees who have been working in the same plant for years and who acquire cardiac disorders. The problem here involves more frequent periodic check-ups and reclassification of the employees to positions compatible with their cardiac defects. This runs into certain complexities, such as labor-union rules regarding seniority rights and job transfers. There are also legal factors that involve aggravation of existing cardiac defects in the worker or danger to his fellow workers or to his company; for example, the railroad engineer in whom coronary artery disease develops. Certainly we must realize that with the increase in the span of life the problem of geriatrics in industry must assume a more important role; the need for continued employment of older workers is obvious. Their skill and reliability should be utilized.

From the Acuff Clinic.

Read before the Section on Preventive and Industrial Medicine and Public Health at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 28, 1950.

This paper and the two previous papers were presented as part of a symposium.

[1] Cited by Sprague, H. B.: Employment of Cardiacs, Indust. Med. 17: 279-282 (Aug.) 1948.

The next question that I should like to take up is the consideration of the placement of the cardiac worker in industry in reference to his disability. It is essential, when a new employee with a cardiac defect presents himself for job placement, or when the old employee comes in for reclassification because of an acquired cardiac defect, that he is classified from an etiological, functional, and therapeutic standpoint. The criteria for these various classifications have been outlined by the American Heart Association. Such classifications uniformly used will eventually bring about a large series of statistics in industry that will act as a guide for the industrial physician.

HYPERTENSION

Hypertension is a common occurrence in industry, if we accept as a measure of normal blood pressure a systolic reading of less than 150 mm.Hg and a diastolic reading of under 90. A few attempts have been made to evaluate how long a hypertensive person may work, but no critical approach to the problem has been made, the reason being that there are so many variables associated with the evaluation of hypertension itself. Smith and Lambie, in reporting their experiences over a period of 10 years, were of the opinion "that the hypertensives had as short a period of disability before death as did the average worker, and their degree of usefulness as employees continued good up until their severance from work." Sprague felt that hypertensive disease coming on in the fifth decade may allow 10 or more years of normal existence. Eventually the hypertensive person exhibits one of the complications of the disorder, and then he is a serious risk. For this reason, my policy has been to have more frequent periodic check-ups on hypertensive workers than on nonhypertensive workers. In a survey of 342 employees, followed for a period of years, it was found that the percentage of abnormal electrocardiograms was in direct proportion to obesity and hypertension. I should like to cite two instances of hypertension in this group of employees that have been interesting to me and demonstrate difficulties in prognosis and management.

Case 1.—A white man 48 yr. old, 5 ft. 10 in. (178 cm.) tall, weighing 181 lb. (82 kg.), had persistent diastolic pressure of 128, with a record of diastolic pressure as high as 170 on one occasion. He was known to have had severe hypertension of at least 10 years' duration. Electrocardiograms that were taken routinely at yearly intervals for four years were essentially the same. The roentgenographic configuration of the heart revealed no change during these years. This man was able to work with no disability and no loss of time from 1945 through 1949. This case is presented to demonstrate that this worker with a high diastolic pressure was able to work for a relatively long period.

Case 2.—A 60-yr.-old white man, 5 ft. 11 in. (180 cm.) tall, weighing 145 lb. (66 kg.), had persistent diastolic pressure of 118 and above for at least three years. How long before this he had had hypertension was undetermined because he had sought the advice of no physician. Roentgenographic examination of the heart for size revealed a minimal cardiac enlargement confined mainly to the left ventricle. Results of routine laboratory procedures were all within normal limits; electrocardiograms were normal in 1947. However, in 1948 there was considerable change in the configuration of the QRST-complexes, which was the first indication that the employee was having cardiovascular difficulties. This man was feeling absolutely well and had lost no time from work; clinically there had been no change in his cardiac status. This particular case represents the value of repeated serial examinations and serial electrocardiograms.

ARTERIOSCLEROSIS

Arteriosclerotic heart disease, including anginal syndrome and myocardial infarction, is a problem of increasing significance and will continue to be so as long as we are dealing with an older age group. Placement of employees who have had myocardial infarction is difficult. Too frequently the employee has been trained in hard manual labor, and the occurrence of a myocardial infarction precludes continuance in that type of work. The difficulties of transfer to another position in view of seniority rights and the difficulties entailed in teaching older employees new responsibilities are other factors. In the few instances in which the employee is fortunate enough to be on a job calling for minimal physical and mental exertion, he does very well for long periods. The employment of new applicants who have suffered myocardial infarction must of necessity be confined to a small and well-selected group. The problem of continued employment of the person with myocardial insufficiency on the basis of coronary artery disease with anginal syndrome is one of careful selective job placement and follow-up observation. The diagnosis at times presents difficulty because of lack of objective evidence, particularly in the case of employees who are attempting to hide physical disabilities and who give an unreliable history for various reasons.

I frequently see men seeking employment who deny any trouble and yet who, after careful study, present pictures such as this. Some authors have recommended that all employees, such as firemen and engineers, who have responsible positions involving the lives of other persons have a routine electrocardiogram made before and after exertion.

RHEUMATIC FEVER

Absenteeism due to recurrences of rheumatic fever and respiratory tract infections frequently precludes the employee from continued work. Of prime importance in this particular group of workers is avoidance of exposure and extremes of temperature. Positions in sheltered locations where work can be done inside in a warm, dry type of environment are to be encouraged. In such circumstances, particularly where there can be freedom from excessive streptococcic infections, this group can do very well. I have had no experience with the prevention of recurrences of rheumatic fever with administration of sulfonamide compounds or pencillin in industrial plants. Psychosomatic cardiac disturbances and cardiac arrhythmias occur frequently and require adjustment, frequent consultation with psychiatrists, and reassurance, along with proper medicinal treatment. Some of the difficulties in the management of cardiac employees in industry are not always due to organic disease but are related to anxiety states arising from conflicts.

In summary, I should like to stress the need for further critical statistical studies of persons with cardiac disorders in industry. My second point is that the cardiac worker with a mild disability is a good employable risk, and my last, that provisions for continued employment of persons of the older age group be seriously considered.

OCCUPATIONAL TUBERCULOSIS IN HOSPITAL AND SANATORIUM PERSONNEL

William G. Childress, M.D., Valhalla, N. Y.

It is a well recognized fact that tuberculosis is not a respecter of persons in any walk of life. It may attack a person of any race or occupation any time from birth until death. There are racial, occupational and environmental differences of susceptibility, tissue reaction and resistance, involving basic and complicated formulas in biometrics, which are as yet only partly understood. We recognize racial susceptibility and resistance, yet who knows what variations, if any, would exist if all races had lived for centuries under identical conditions? Influences not wholly understood are exerted in age and sex groups. The virulence of the organism and the size of the infecting dose necessary to cause disease are also significant factors. All agree that without the presence of the tubercle bacillus in the working environment or the body, tuberculosis cannot develop as an occupational hazard. Conditions of employment may conceivably cause activation of a latent tuberculosis infection, but they are difficult to evaluate under normal conditions of employment. Therefore, in attempting to evaluate tuberculosis as an occupational hazard, one must keep in mind the above-mentioned factors and other basic considerations too numerous to discuss here, but the first line of attack must be against the tubercle bacillus in areas of employment.

CONDITIONS OF EXPOSURE

Perhaps there is no more incriminating evidence of causal relationship in the thinking of the public, and most physicians, than the development of the disease in a person known to have been exposed to it in a hospital or sanatorium. Yet, this is not prima facie evidence of causal relationship. There may be, and sometimes are, other opportunities for infection. Moreover, where rigid protective techniques are practiced, the danger may be greatly reduced or eliminated. Conversely, there is not prima facie evidence sufficient to exclude causal relationship when the disease develops in an employee who is in contact with unrecognized tuberculosis among patients or personnel, for when tuberculosis is unrecognized it is impossible properly to segregate patients and institute protective measures. How, then, may we proceed in an attempt to arrive at a reasonably accurate answer in fairness to all concerned? There is no better place than a well administered hospital in which to work out acceptable standards for fairly evaluating causal relationship in tuberculosis developing among hospital personnel. There are conditions of employment that point accusingly to causal relationship, others that defy exclusion of the possibility and those that may not preclude theoretical possibilities but make them appear unlikely.

TYPES OF CLAIMS

In our experience claims allowed or disallowed fall into four general groups. In the first, a young person, for instance a student nurse who enters employment with a family history negative for tuberculosis, negative tuberculin reaction and normal chest x-ray, is intensively exposed in the routine of duty for a few weeks or months. Her tuberculin reaction becomes positive, and eventually a tuberculous lesion develops. Since there are no other known sources of contact, she is reasonably considered to have acquired disease as a result of occupational exposure. All claims in this group have been allowed in our experience. In this same group is the person who has a family history of tuberculosis, but who has a negative tuberculin reaction and normal chest x-ray at the time of employment and in whom disease subsequently develops under the conditions described above. This person may also be considered to have acquired disease as a result of occupational exposure. It may be assumed that, even if there were a previous infection, it had cleared spontaneously and superinfection developed for all intents and purposes in completely healthy tissue, even if chest x-rays taken during employment revealed evidence of healed primary infection. In our experience, claims in this group have been allowed.

In the second group a person enters employment with a positive tuberculin reaction and a normal chest x-ray or evidence of healed primary infection only, without massive parenchymal involvement. If disease subsequently develops, this person may, and often does, become a subject of medical controversy. Exogenous superinfection or reinfection or endogenous exacerbation cannot be determined clinically, and contemporary pathologists,[1] agree that exogenous superinfection or reinfection may occur, and there is no constant pattern that distinguishes primary from reinfection tuberculosis clinically or pathologically. It must, then, be presumed that exogenous superinfection or reinfection is possible in any case, if indeed not probable. In our experience all such claims have been allowed when other contact or adverse working conditions could not be demonstrated.

A person in the third group enters employment with or without a history of tuberculosis or contact, has a positive tuberculin reaction and x-ray evidence of apparently healed or latent parenchymal disease. If the disease subsequently becomes active, this person is usually presumed to have reactivated disease or endogenous reinfection, despite other possibilities, because this type of tuberculosis is prone to reactivate under normal conditions of life independent of occupation. Only one claim has been allowed in this category in our experience.

The fourth group is largely made up of persons making false or questionable claims in an attempt to collect benefits to which they are not entitled. They gain employment by misrepresenting the status of their disease or by the employer's unawareness of the disease. They are usually represented by counsel. None of these claims has been settled in favor of the claimant in our experience.

[1] Opie, E. L.; McPhedran, F. M., and Putnam, P.: Am. J. Hyg. **23**: 530 (May) 1936. Pinner, M.: Pulmonary Tuberculosis in the Adult, Springfield, Ill., Charles C Thomas, Publisher, 1945, p. 173. Rich, A. R.: The Pathogenesis of Tuberculosis, Springfield, Ill., Charles C Thomas, Publisher, 1944. Terplan, K. L.: Am. Rev. Tuberc. (Supp.) **42**: 1 (Aug.) 1940. Medlar, E. M.: Am. Rev. Tuberc. **55**: 517 (June) 1947. Lurie, M. B.: Am. Rev. Tuberc. (Supp.) **44**: 1 (Sept.) 1941.

In the first two groups, time is an important factor, since detection of clinical disease may not immediately follow the infection it results from. In most instances claims allowed were those of persons in whom clinical disease had developed within a year after exposure or conversion of the tuberculin reaction. Awards in compensation claims are not made on clear scientific proof, which is almost always lacking, but on what appears to be the most likely proof in light of the evidence produced.

Attempts to evaluate fairly employees under consideration for workmen's compensation claims at Grasslands and experience in giving medical testimony in compensation court lead one to the conclusion that there are justifiable differences of opinion in any given case for reasons that have been mentioned. As long as honesty of conviction prevails, there is no place for intolerance of another's point of view. Yet, there is reason to believe that professional bias prevails at times. Justice in some instances will have to await further advances in the basic sciences and the institution of sound administrative practices. In the meantime, we should proceed along logical and proved lines of attack in an effort to reasonably establish or exclude causal relationship for employees in whom tuberculosis develops in the line of duty.

RECOGNITION AND ACCEPTANCE OF HAZARD

The medical profession and hospital administrators have been slow to recognize and accept the existence of tuberculosis as an occupational hazard, and few hospitals avail themselves of the full opportunity for case finding among hospital patients and employees. Fortunately, attitudes and practices are changing for the better. There is an increase in the use of acceptable methods of case finding in hospitals, and now 23 states, Alaska, Hawaii, the District of Columbia and the United States Government (for civil employees) have full coverage for tuberculosis as an occupational disease, and 18 states have limited coverage, principally for employees in institutions. I am informed by the director of the Division of Labor Standards, U. S. Department of Labor, that the lack of general coverage or of specific mention does not necessarily mean that a hospital worker contracting tuberculosis would not receive workmen's compensation, because there have been sporadic court decisions that the infection is an "accident."[2] In some instances there is the limitation that the disease, to be compensable, must be characteristic of the employment.

Mr. G. M. Ingersoll, acting chief of the Legislation Branch, Department of Labour, Canada, informs me that two provinces, British Columbia, in 1943, and Ontario, in 1950, added tuberculosis by statutory regulation to their schedules of industrial diseases for which workmen's compensation is payable, and at the 1950 session of the legislature, Manitoba amended its definition of industrial disease to include any other diseases (in addition to those listed in the schedule to the act) peculiar to, or characteristic of, a particular industrial process, trade or occupation.[3] This definition could, therefore, include tuberculosis.

GRASSLANDS HOSPITAL EXPERIENCE

In 1932 when the new tuberculosis program was begun, we started preemployment and periodic chest x-ray examination of all employees in the tuberculosis division of Grasslands Hospital.[4] Tuberculin testing was optional at that time but was made compulsory in 1941 as an aid in evaluation of compensation claims of persons in whom clinical disease had developed. In 1938 periodic chest x-ray examination was instituted for employees throughout the hospital, and, since Jan. 1941, chest x-rays have been obtained on patients admitted to the hospital for conditions other than tuberculosis.[5] Tuberculin testing as indicated and chest x-rays are done at six month intervals on professional groups in the hospital, including student nurses.[6] When closer observation is indicated, employees are followed in the chest clinic. Chest x-rays are made at yearly intervals on nonprofessional employees not in close contact with patients.

RESULTS

Early observations revealed a significantly higher incidence of tuberculosis among those working in close contact with known sources of infection than among those who were not, regardless of age or other considerations. This has been confirmed by later observations. Continuous case finding as outlined and follow-up of patients have resulted in the accumulation of valuable data. Since 1932, among 7,901 persons, 78 without previous evidence of significant tuberculosis, many without evidence of infection, were found to have active tuberculosis during employment and while under observation. Sixty-five of these cases developed in a group of 3,486 employees with 9,750 exposure years, a rate of 0.66 per 100 per year, and 13 developed in a group of 4,415 without known exposure, a rate of 0.13 per 100 per year. It is significant that among the 78 patients in whom clinical disease developed there were 13 physicians, 27 student nurses, 20 graduate nurses and five attendants, revealing that a greater danger exists for those in close contact with the patient. The annual attack rate in this series for professional groups is approximately 1 per 100, which is higher than the rate of 0.66 per 100 for all employees with known exposure. Somewhat higher or lower annual attack rates have been reported in nursing and hospital groups by others.[7] All are higher than the annual attack rate of 0.2 to 0.3 for clerical employees in the Metropolitan Life Insurance Company, reported by Reid,[8] and than our unexposed group, in which the rate is 0.13.

DISCUSSION

With the recognition of tuberculosis as an occupational hazard by so many governmental agencies in the United States, Canada, and the territories, it becomes increasingly important to recognize forces that contribute to the hazard. As stated in the introduction, there are many influencing factors that need clarification. It does appear that a major contributing cause is the opportunity for intensive exposure to the tubercle bacillus. However, the danger of exposure should not be overly stressed, because most (98.2 per cent) of those working in close contact during the period did not develop disease, indicating a high degree of native resistance.

[8] Reid, A. C.: J. Indust. Hyg. & Toxicol. 22:408 (Nov.) 1940.

In reporting on accident hazards and costs in service industries, Donlon [9] reports that of 116 cases of occupational tuberculosis in 1947 for all service activities, 109 occurred in hospitals and other health services where exposure is greatest. In our series, from 1935 through 1948, 46 claims for workmen's compensation were allowed on the basis of causal relationship, and 13 were disallowed. Our experience amply supports the view that occupational tuberculosis develops where there is a chance for intensive exposure. All 46 who were awarded workmen's compensation worked in heavily exposed areas where causal relationship could not be excluded. The tuberculin reaction was positive in 19, negative in 20 and unknown in seven at the time of employment, which shows that the presence or absence of a previous infection has not materially influenced the decision of the courts in the evaluation of these claims.

Occupational tuberculosis results in unnecessary suffering and loss of life, for, despite a good end result for 75 per cent, 25 per cent have died or are still incapacitated from active tuberculosis, in our series of 78. In addition, the expense involved is excessive in loss of time and cost of treatment and compensation. Therefore, efforts to eliminate the hazard justify any expense involved. In November 1948 we added to our control program BCG vaccination of tuberculin-negative professional and nonprofessional groups working in heavily infected areas. To date no case of tuberculosis has developed in the vaccinated group. This is an interesting observation, although I make no claim for its clinical significance, for neither has a case of tuberculosis developed among the positive reactors during this interim. There has been no significant difference in the annual attack rate in the tuberculin-positive or tuberculin-negative groups in this series.

SUMMARY AND CONCLUSIONS

In our experience a tuberculosis hazard exists only for employees in close contact with tuberculosis in hospitals and sanatoriums. The hazard should be recognized but not overly emphasized. The higher rate is partly swelled by repeated reexamination of persons over a period of years. Figures for comparison of similar segments of the population in other occupations are meager. Therefore, the hazard remains in some degree an unknown factor. It should be stressed that clinical disease did not develop in 98.2 per cent of employees exposed in this study, and 28.6 per cent escaped infection sufficient to convert the tuberculin reaction. Our experience indicates that tuberculosis as an occupational hazard may be reduced, and possibly eliminated, by adequate case finding, isolation of infectious cases, the use of sound protective measures for professional and allied workers in close contact with infectious patients or material and BCG vaccination of tuberculin-negative persons required to be in contact with tuberculosis in the course of their employment.

TREATMENT OF TYPHOID IN PREGNANCY WITH CHLORAMPHENICOL (CHLOROMYCETIN®)*

Charles S. Stevenson, M.D., Anthony J. Glazko, Ph.D., E. Clark Gillespie, M.D.
and
John B. Maunder, M.D., Detroit

Typhoid, in recent years, has been a rare but nevertheless serious complication of pregnancy. Spontaneous abortion or premature labor has occurred in 60 to 80% of such cases. Fetal death in utero is common and has, in some cases, been demonstrated to be due to transmission of the typhoid bacilli from the mother to the fetus.[1] When the disease has been present in the mother for a few weeks, approximately one-half of the fetuses have become so infected. Maternal mortality has been about 15%, while about three-quarters of the fetuses and infants generally have been lost.

In view of the recent reports of the successful treatment of typhoid with chloramphenicol [2] and the fact that we might sometime expect to treat a pregnant woman who had typhoid fever, we undertook to study the transmission of chloramphenicol from the maternal blood to the fetus.

We wished to determine whether chloramphenicol penetrates the human placental barrier in sufficiently high concentration to have an antibiotic effect in the blood of the fetus.

METHOD

A 1-gm. dose of chloramphenicol in the form of four 0.25 gm. gelatin capsules was given by mouth to 20 parturient women from one-half hour to two and three-fourths hours before delivery. Samples of venous blood from the mother and from the veins of the umbilical cord of her infant were taken at the time of delivery. After clotting, the serum was separated by centrifugation and was analyzed by one of us (A. J. G.) for chemical derivatives of chloramphenicol and biologically for the presence of the

antibiotic itself; arylamines were assayed by a modification of Bratton and Marshall's method,[3] and total nitro compounds by reduction with titanium chloride, followed by diazotization and coupling.[4] Chloramphenicol, or unaltered antibiotic, was assayed by microbiological procedures against Shigella sonnei.[5]

RESULTS

Fetal cord blood (venous) was found to contain significant quantities of the antibiotic. The average level of chloramphenicol in the cord blood was 72% of that found in the maternal blood. An appreciable concentration of the antibiotic was present in the cord blood within one hour of ingestion of the drug by the mother, and the concentrations of chloramphenicol in the fetal and maternal veins were roughly the same after two and one-half hours. We therefore judged that chloramphenicol therapy of typhoid in a pregnant woman should be as effective for the fetus as for the mother and, if started early enough in the course of the disease, should prevent fetal death in utero and the subsequent onset of premature labor. We felt that the known high mortality for mother and fetus in typhoid should be reducible to extremely low levels among patients to whom chloramphenicol could be given before the disease had made great inroads. When we had completed our studies, a paper on the subject was published by Ross and associates.[6] In it they stated that "chloramphenicol was observed to pass through the placental barrier and was present in cord blood in a concentration of 50 to 75% of that observed in the maternal blood."

We had no more than completed our studies on the placental transmission of chloramphenicol when a woman in her seventh month of pregnancy and with a severe febrile disease was admitted to Herman Kiefer Hospital, communicable disease division.

REPORT OF CASES

CASE 1.—L. C., a 25 year old Negro woman, was about seven and one-half months pregnant when admitted to the hospital on Sept. 29, 1949. She complained of severe headache, backache, dysphagia, fever, and malaise, all of which had been present for about six days. On Sept. 25, because of the same complaints, a lumbar puncture had been performed in the outpatient department of the hospital, and studies of the fluid indicated the absence of meningitis. On Sept. 27 she had noted regurgitation of swallowed water and subsequently vomited frequently. Her past history was essentially noncontributory. She had given birth to seven children, all girls, in the previous 11 years.

When she was admitted her temperature was 104 F., pulse 134, respiration 40, and blood pressure 128/80, and the spinal fluid showed 14 cells per high power microscopic field. The Pandy test was negative, and the sugar was 00+++. Her red blood cell count was 3,330,000, hemoglobin 55%, leucocyte count 5,950, with 83% polymorphonuclear cells, 14% lymphocytes and 3% monocytes. She was very obese, somewhat somnolent, and her positive physical findings were an injected pharynx, a moderately rigid neck and back, and a pregnant uterus that extended two-thirds of the way from the umbilicus to the xiphoid. The first impression was that she had nonparalytic poliomyelitis in addition to being about 30 weeks pregnant.

She vomited frequently, was receiving parenteral fluids, and her condition remained essentially unchanged. On Oct. 2, when seen in obstetric consultation by one of us (E. C. G.), she was found to be complaining of severe upper abdominal cramps and nausea, and she had vomited several times that day. At that time she had a temperature of 103.8 F. and a pulse rate of 120. She was well hydrated and well oriented. Marked upper abdominal tenderness and some rebound tenderness were present. The diagnosis of typhoid was suggested. She had been receiving penicillin injections and sulfadiazine by mouth.

On Oct. 3 the Widal reaction with the H antibody was negative, but that for the O antibody was positive in a dilution of 1:80. Agglutination tests for paratyphoid A and B and for brucellosis were negative. Blood for culture had been taken, and on Oct. 5 gram-negative rods were found growing in the culture; the next day it was determined that they were typhoid bacilli. Chloramphenicol treatment was begun at once. Since the patient was vomiting, the capsules were punctured at several points with a pin and, following a rinsing out of the sigmoid and rectum, were inserted into her rectum; she received 1.5 gm. every eight hours.

Thirty hours after the commencement of chloramphenicol therapy the patient's temperature began to fall from an average high of 102.6 F., and within 36 hours it reached 98.2 F. There was also a marked symptomatic improvement during this period in that she became alert, stopped vomiting, expressed hunger and ceased to have abdominal pain. Because of a low hemoglobin she was given two 500-cc. blood transfusions. The fetus remained active. Defecation was normal, and she shortly began to eat a full diet.

Stools taken for culture on Oct. 5 were negative for typhoid bacilli, while those taken on Oct. 18, 21 and 22 were positive. Cultures of stools taken on Oct. 29 and Nov. 7 were negative. All urine cultures were negative for this organism.

Chloramphenicol therapy was stopped on Oct. 18, after 12 days of continuous therapy at the rate of 4.5 gm. per day, or a total dosage of 54 gm.

The patient was up and walking about the ward for the last week of hospitalization and was discharged on Nov. 18 in good condition. At her discharge the fetus was active and lay in right occiput transverse position with its head not engaged. Her blood pressure was 128/70, and her urinalysis was negative.

On Dec. 26 the patient was readmitted to the communicable disease division of Herman Kiefer Hospital in active labor. Because she was a potential typhoid carrier she was kept in isolation. After three hours of labor she spontaneously delivered herself of a 4,320 gm. female infant who cried and breathed at once. The infant was normal and was given regular formula feedings. All tests made on it were negative for typhoid. The mother had a normal postpartum course, and was discharged with her infant on Dec. 31.

Repeated periodic cultures of the stools of both mother and infant, from the time of delivery, have been negative. The last materials for culture were taken on March 8, 1950.

CASE 2.—M. L., a 23 year old nulliparous graduate nurse, whose last menses began on March 7, 1950, was admitted to Grace Hospital on May 24 with a temperature of 100.6 F. and a pulse rate of 100. For three days prior to admission she had noted a mild painful urgency to defecate and slight deep pelvic discomfort during defecation. The pain was spasmodic, periumbilical in location, and was relieved by defecation. The stools had been of normal consistency, but expulsion was noted to be unusually rapid and forceful. She had not noted any blood or mucus in her stools.

[6] Ross, S.; Bischoff, H.; Preisser, W., and Orr, W.: Some Observations on the Absorption and Excretion of Aureomycin and Chloramphenicol, J. Clin. Invest. **28**: 1050 (Sept. pt. 1) 1949.

Her pregnancy had otherwise progressed normally until the night of May 23 when she noted the fairly rapid onset of a sharp, low frontal headache, with "burning" of the eyes and some malaise. She went to bed early but was awakened at 6 A. M. by nausea and a severe headache. She vomited several times and, feeling weak and ill, returned to bed. She next awakened at 10 A. M., and, finding some bright red blood stains on her nightgown, discovered slight vaginal bleeding. There were no uterine cramps, but she noted recurrence of the periumbilical cramps and her headache and malaise persisted.

She was admitted to the hospital by one of us (C. S. S.) that afternoon, at which time she exhibited a flushed face and obvious malaise. The positive physical findings were a definite gravid firmness of the breasts, increased frequency and pitch of the small-bowel sounds on abdominal auscultation, the presence of a small amount of dark brown and somewhat watery vaginal discharge, and, on rectal examination, the enlargement of the uterus to the size of an eleven weeks' pregnancy. The uterus was tense, lay between anterior and middle position, and the ovaries were normal. Acute enteritis of an unknown type and threatened miscarriage of an eleven weeks' pregnancy were suggested.

Because of the obvious signs of acute enteritis, the severe malaise, and the fact that one of us, the examiner (C. S. S.), had started to write this paper and had typhoid in mind, a Widal test and stool cultures were ordered, and complete bed rest and isolation were prescribed for the patient.

The results of the Widal reaction were obtained on May 26, the O antibody was positive 1:320 and the H antibody positive 1:80. Agglutinations for paratyphoid A and B and for brucellosis were negative. The taking of blood for culture had also been intended, but, by error, was omitted at this time. Stool cultures were negative for typhoid bacilli. It was judged that the patient had typhoid, and chloramphenicol therapy was begun on the afternoon of May 26. She received 1 gm. during the first two hours; 0.5 gm. was then given four times that day. The following day her temperature was 98.2 F. and the pulse rate was 72. She no longer had headache or malaise, and the abdominal cramps had ceased. On May 28 and 29 she remained symptom free, but had one temperature reading of 100 F. From then on her temperature and course were entirely normal, and she had no further vaginal bleeding.

On June 4 the patient was transferred to the communicable disease division of Herman Kiefer Hospital, where her chloramphenicol therapy was continued. The Widal test was repeated; the reaction with the O antibody was negative, but that with the H antibody was positive in a dilution of 1:640. Other agglutination tests were negative. She had no uterine cramps or vaginal bleeding and was discharged to her home on June 6. She received chloramphenicol for 12 days, a total dose of 25 gm. She remained well at home until June 18, when she again had some slight vaginal bleeding and also some lower mid-line abdominal cramps. She was put to bed, but the following day miscarried a relatively small and collapsed ovisac containing a markedly macerated and amorphous fetus measuring about 2.5 cm. in length. The ovisac was complete and curettage was not performed. Following this she had an uneventful recovery.

COMMENT

These two cases demonstrate not only the efficacy of chloramphenicol in the treatment of typhoid, but also the possibility of saving the fetus when the drug is given in proper dosage and begun early enough in the course of the disease in a pregnant woman. The first patient received adequate dosage, and the fetus continued on through the pregnancy. All studies made on it following delivery were negative for typhoid. We cannot know whether it ever did develop intrauterine typhoid but, since it was entirely normal at and following delivery and since chloramphenicol therapy was commenced on the 12th day of the patient's illness, it is probable that the fetus had not yet contracted this disease at the time chemotherapy was begun.

The second patient began to receive chloramphenicol on the fourth day of her disease, but, in retrospect, it is believed that she was not given an adequate daily dosage of this drug. She should have received 4 gm. instead of 2 gm. daily. Even this dosage, however, probably would not have permitted the fetus to survive, since we have long known of the relatively great frequency of fetal death during the first trimester of pregnancy in women who have a systemic infectious disease. In this case the extreme maceration of the fetus and its relatively small size probably indicate that it died in the first few days of the disease, and the effect of the chloramphenicol had probably come too late to save it. Furthermore, the signs of threatened miscarriage and the onset of typhoid occurred simultaneously, and we cannot be certain that fetal death in utero in this case occurred as a direct result of the typhoid.

CONCLUSIONS

Typhoid during pregnancy, although very rare, when not treated with a specific chemotherapeutic agent can result in fetal loss in 60 to 80% of cases, and the maternal mortality may run as high as 15%.

Chloramphenicol has proved to be a most efficacious chemotherapeutic agent in the immediate treatment of typhoid and has resulted in a marked lowering of the mortality rate of this disease.

It has been demonstrated, in pregnant women at term, that chloramphenicol passes from the maternal to the fetal blood stream in one hour following its ingestion, that it there attains a concentration equal to three-fourths of that in the maternal stream, and that the blood concentrations of mother and fetus are relatively the same after two and one-half hours.

Two cases of typhoid in pregnancy, in which chloramphenicol therapy was utilized, are presented, and the results are considered to be quite satisfactory.

It is believed that the proper dosage of chloramphenicol, in treating such cases, should be a minimum of 4 gm. daily over a period of 12 days.

Fetal Malformation.—Whilst the genetics of some rare deformities are clear, the most common conditions are difficult to attribute to unique causes. Many types of adverse circumstances, genetical or environmental acting either separately or in collaboration, are implicated. At the critical stages of embryonic development during the first two to three months, similar pathological reactions leading to malformation may be induced by quite diverse causes. The present state of knowledge is very incomplete but advances are now rapidly being made. The fact that the causes of fetal malformations are multiple and that so many environmental causative influences are being detected, is leading to a much more promising view of the possibilities of prevention than was entertained some years ago, when almost all congenital defects were believed to be due to inexorable heredity.—L. S. Penrose, M.D., Heredity and Environment in the Causation of Fetal Malformation, *The Practitioner,* May, 1951.

NATURE OF WATERHOUSE-FRIDERICHSEN SYNDROME

REPORT OF CASE WITH SUCCESSFUL TREATMENT WITH CORTISONE

Jack Nelson, M.D.
and
Norman Goldstein, M.D., New York

The Waterhouse-Friderichsen syndrome has long been notable among infectious diseases for having a fundamentally twofold character: an acute infection together with profound circulatory collapse. It is the conjunction of these two factors that has given the syndrome an intensity and a rapidity of progression unparalleled among bacterial diseases. "No other infection slays so quickly," said Herrick.[1] And Martland,[2] reporting from his experience as a medical examiner, was able to collect 19 cases which had been referred to his office after sudden, unexplained, and sometimes suspicious death in children and young adults. Many of these patients were found dead in their beds; others died on arrival or within a few hours after arrival at the hospital. Not only was death swift; it was also certain. In 1938 Christian,[3] long a close student of this disease, wrote that all known cases had been fatal, generally in less than 24 hours.

However, shortly thereafter, with the advent first of the sulfonamides and then penicillin, cases of Waterhouse-Friderichsen syndrome ending in recovery began to be observed. The first of these was the one reported by Carey[4] in 1940. From that time until the present there have appeared occasional instances of cure. Nevertheless, it has remained evident, both from the relative scarcity of cases with recovery and from the experience of one of us (J. N.), that the Waterhouse-Friderichsen syndrome has continued to be a serious condition with a grave outlook. Surely it has not shared in the remarkable improvement of prognosis exhibited by meningococcic infections in general during this period, which has witnessed rates of recovery ranging from 95[5] to 98.5%.[6]

There is little doubt that the reason for this disparity lies in the fact that together with the severe, sometimes fulminating, infection there exists a most profound circulatory collapse. Indeed, one might almost say that these patients would recover routinely, as do the others with meningococcic infection, if they could be kept alive through the phase of shock. Toward this end have been employed such nonspecific measures as infusion of saline solutions, plasma, and blood, and the presumably more specific therapy of adrenal replacement.

With regard to the former there is general agreement that neither infusions nor transfusions are of much avail. The investigations of Ebert and Stead[7] into the nature of collapse in bacterial infections have shown that it is not of the same character as the shock following hemorrhage or trauma; it is not related to hemoconcentration, nor does it result from diminution of venous return to the heart. Neither is aid from such measures to be expected therefore, nor has it been obtained by those who have used them.[8] Although adrenal cortex substances, which have heretofore been available in the form of desoxycorticosterone and aqueous extract of the adrenal cortex, have seen sporadic use during the past decade, it has been difficult to determine whether and to what extent they have aided in treatment. Their employment in combination with antibacterial agents has resulted in prolongation of life and sometimes in recovery; however, their effect has been far from striking and has been considered by many to be negligible. They have been administered, of course, as replacement therapy, but their physiological scope is limited, and it may be questioned whether they do indeed constitute adequate replacement. Beyond this, many have raised the larger question whether adrenal insufficiency plays any significant part in the clinical picture.

NATURE OF THE CONDITION

The Waterhouse-Friderichsen syndrome has retained its eponymic designation largely because various investigators have differed regarding both its pathology and its pathogenesis. It is caused by meningococcic invasion in almost all cases, although other organisms such as staphylococci, streptococci, and pneumococci occasionally have been found responsible.[9] It has an incidence of from 2 to 4% of the cases of meningococcic infection,[10] with a considerable predilection for children; Lindsey[11] reported that in 90% of the known cases the syndrome occurred in children under the age of 9 years.

Clinical Picture.—This is remarkable for the intensity and the rapidity of progression of which we have spoken. The invasive phase resembles that of many acute infections, with fever, malaise, headache with generalized aching, sometimes accompanied with vomiting or chills;

[11] Lindsey, in Christian.[3]

these often elicit a diagnosis of grip. Then, in a matter of four to 12 hr., there appear a massive and widespread hemorrhagic rash and severe toxicity, often with an abrupt rise of temperature to higher levels and sometimes convulsions. There follows, almost under the eyes of the observer, a profound collapse which features, in addition to the signs of hypotension, a striking cyanosis with lividity of the dependent parts which is almost deathlike. Irreversible shock with coma follows hard upon this, with death itself occurring usually within 24 hr. after onset of the illness. Signs of meningitis may be present, but usually they are not pronounced and may even be entirely absent, chiefly for the reason that the syndrome evolves so rapidly.

Though it has not been possible to make more than sporadic investigation of the chemical alterations in the blood, certain facts are evident. Azotemia occurs in almost all cases, presumably in consequence of the combined impact of dehydration and collapse on renal function. Marangoni and D'Agati [12] have reported two cases with the renal findings of lower-nephron nephrosis. Hypoglycemia regularly is encountered [13] and has been considered a specific consequence of adrenal cortex damage. It is interesting to observe, however, that the serum electrolytes, which have been the object of most attention, undergo relatively little alteration. Although some cases exhibit the diminution of sodium and chloride and the elevation of potassium, which are characteristic of lack of adrenal cortex function, numerous observers have found these constituents to be either normal or little changed therefrom.[14]

Pathological Examination.—The body as a whole bears evidence of a brief, severe infection, frequently with the additional changes resulting from a state of shock. There are acute passive congestion of the lungs, toxic degeneration with cloudy swelling of the liver, kidneys, and often the myocardium, and acute splenic tumor; further, there may be incipient inflammation of the meninges. More marked than in most infections is the considerable engorgement of the smallest vessels throughout the body. This is doubtless responsible, at least in part, for that remarkable shifting cyanosis which may even precede the appearance of shock. Further, it is likely related to the occurrence of hemorrhages which are so characteristic of meningococcic infection, these being found as multitudinous small purpuric areas not only in the skin but throughout the parenchymatous organs and on the serosal surfaces. Hill and Kinney,[15] in a careful pathological study of such skin lesions, have demonstrated that the dilatation, chiefly of the capillaries but also in some degree of the arterioles and venules, is followed by swelling and breakdown of the endothelium and by large numbers of platelet thrombi. The ischemic necrosis of the subserved areas leads to hemorrhage into the perivascular spaces. The additional possibility is considered by these authors that a secondary thrombopenia incident to the aggregation of platelets into thrombi may contribute its share to the hemorrhagic tendency. Alternatively, bacterial embolization to the small vessels may initiate a similar sequence. It should be noted, however, that the hemorrhagic lesions, except possibly in the rare instances of gross bleeding into the intestine, pleura, or subdural space,[16] are not of such magnitude as to be capable of causing vascular collapse through the mechanism of blood loss.

Pathologic Changes in the Adrenals.—The agreement regarding these foregoing clinical and pathological features, however, does not obtain with respect to the adrenal glands; for there has arisen considerable difference of opinion among various investigators regarding the pathological changes to be found in the adrenal cortex and their role in the production of the clinical syndrome. In the early reports before the turn of the century, Voelcker,[17] Battin,[18] and Garrod and Drysdale,[19] described the occurrence of gross adrenal hemorrhage sufficient to destroy the entire gland and to convert it into a mass of blood. In 1901 Little [20] construed a relation between this pathologic change and the occurrence of collapse, although he speculated on the adrenal medulla in this regard. As the functions of the different parts of the gland became increasingly defined, interest centered on the cortex, but the relation between the adrenal pathology and the shock continued to be asserted. By 1936 Aegerter [21] was able to collect 55 cases of the Waterhouse-Friderichsen syndrome, with gross hemorrhage into both adrenals in 51 cases and into one adrenal in three cases.

However, in 1942 Williams [22] reported that of 17 cases of the syndrome adrenal hemorrhage was found in only nine. Martland,[2] Thomas and Leiphart,[23] Schwarz,[24] and Daniels,[5] the last-named on the basis of experience similar to that of Williams, have expressed the belief that the clinical evolution of the Waterhouse-Friderichsen syndrome results from the fulminating sepsis, that adrenal hemorrhage is not an invariable concomitant, and that when it does occur it is incidental to the total pattern.

It remained for Rich and others [25] to bridge the difference between these points of view by a more intimate study of the pathological changes than had been made previously. On gross observation his experience paralleled that of Williams, for, notwithstanding the regular occurrence of adrenal hemorrhage among infants, most adults dying of the disease had either no hemorrhage or but insignificant petechial bleeding. However, microscopic examination revealed a remarkable type of damage which he termed "tubular change," an alteration which appears to be but one aspect of the severe degeneration of the adrenal cortex which is uniformly found in those instances in which hemorrhage has not obliterated all evidence. This degeneration is apparently related to the fulminating nature of the process, being more marked in this than in other infections. Moreover, it does not result from vascular collapse, inasmuch as it is not to be found after shock following blood loss or trauma. Beginning in the fasciculus but proceeding to neighboring zones, the pyknotic degeneration and loss of substance of the cell cords opens them to dissection by hemic elements and to conversion into tubular structures filled with blood cells and fibrin. Together with this there is a shrinkage of the cords away from the perivascular spaces, with ensuing loss of support for the blood vessels. These changes, in themselves indicative of cellular damage of such degree as seriously to impair the functioning of the adrenal cortex, occur in the context of the vascular dilatation and capillary damage already described. With the adrenal cortex the site of so rich a blood supply, it is clearly a short step to hemorrhage into and about the cell cords and, indeed, to gross bleeding, which inundates the organ and destroys it completely. It becomes evident, then, that the pathological change may be viewed as a process advancing from cellular degeneration toward obliterating hemorrhage, or as stopping at any point along the way.

Pathogenesis.—These considerations may permit a better understanding of the Waterhouse-Friderichsen syndrome and help reconcile the diverse opinions which exist regarding its pathogenesis. Those who have doubted any specific relation of adrenal damage to the clinical picture have been impelled to this view not only by the finding, already discussed, that gross hemorrhage is often lacking but also by the observation that collapse supervenes with great rapidity and in the face of maintained electrolyte levels in the blood serum. It clearly would appear necessary to examine these questions not in terms of hemorrhagic destruction but in those of adrenal function in relation to the changing needs of the body.

Dogs subjected to adrenalectomy [26] display anorexia followed by vomiting and diarrhea; their initial listlessness gives way to weakness, hypotension, coma, and finally death in a state of shock. This deterioration takes place relatively slowly, and the animals survive about seven days. Unlike the removal of the adrenal gland in an otherwise normal animal, however, it is evident that in the Waterhouse-Friderichsen syndrome the exhaustion of the adrenal cortex occurs in the full tide of a severe infection and as a result of the stress imposed by that infection. Zwemer [27] has shown that the cells of the adrenal cortex, especially in the outer fasciculate and glomerular zones, contain lipid globules; these have been closely identified with the stored hormone.[28] Sarason [29] and others [30] have pointed out that both in experimental animals under metabolic stress and in persons with serious infection there occurs a pronounced diminution of the lipid deposits which, in cases of fatal infection, may be completely exhausted.[31] That this loss of lipid substance is not merely a toxic effect of stress but indeed truly represents the increased utilization of the hormone by the body under stress is revealed by the study of Thorn and associates.[32] They showed that in patients under treatment with desoxycorticosterone for Addison's disease the advent of infection necessitated the administration of increased amounts of the hormone. It is also revealed by Shipley's finding of increased urinary cortin after infection or injury.[33] Under conditions of stress the stored hormone enters the circulation and the cells degenerate from their normal globular condition to a granular or homogeneous one. Selye [30b] and Zamcheck [34] have demonstrated that under marked stress this degeneration may take the form of widespread cytolysis leading to the "luminal" or "tubular" change of Rich. Thus, the available store and the source of further supply of the cortical hormone are abolished, and the gland suffers physiological ablation precisely when the need for its product is greatest. It is this crisis which precipitates the collapse in all its speed and severity.

The relative maintenance of electrolyte levels, to which allusion has already been made, constitutes a most interesting finding in the face of the presumed cortical deficiency. It has been conjectured that the very rapidity with which the syndrome advances may preclude alteration in the electrolyte balance of the serum on a large scale. It appears likely, however, that other factors may be at work in addition. Both febrile dehydration and shock, with its alterations of renal function, serve to concentrate the constituents of the blood. Hence, the maintenance of electrolytes must be understood in relation to the several, and in some cases mutually contradictory, factors which help determine the resultant levels. Thorn,[35] writing of acute adrenal insufficiency precipitated in patients with potential insufficiency by the stress of surgery or trauma, adds:

> Under these circumstances, operation may easily precipitate an acute adrenal crisis. Signs and symptoms of adrenal failure are most likely to develop twelve to forty-eight hours post-operatively. . . . The striking dehydration [i. e. of adrenal origin] and alteration of serum electrolytes so characteristically seen in chronic adrenal insufficiency may not be present in these acute cases.

In the light of these considerations the following case of Waterhouse-Friderichsen syndrome is presented. It is the first, to our knowledge, in which cortisone has been used.

REPORT OF CASE

An 11-yr.-old boy complained one day of nasopharyngitis and mild epigastric pain. That evening he awakened from a sound sleep with nausea and severe vomiting, and he felt feverish. Some six hours later he suffered a generalized convulsion followed by stupor. He was admitted to the Lincoln Hospital on the morning of June 19, 1950.

At the time of admission he appeared a small boy who was acutely and severely ill with a temperature of 105.4 F. and the facies of shock. His pulse, at a rate of 140 a minute, was thready, and the blood pressure, obtained with difficulty, was 70 mm. of mercury systolic and 20 diastolic, though the heart sounds were of fair quality. He was in stupor and could be roused but momentarily by supraorbital pressure. His respiration rate was 30 a minute, and there was moderate cyanosis of the lips and nail beds. The skin and mucous membranes were the site of a widespread petechial eruption, and there was a diffuse tonsillopharyngitis. Neither meningeal nor focal neurologic signs were in evidence.

Lumbar puncture made at the time of admission elicited a clear fluid containing 20 mononuclear cells and 21 mg. of protein and 76 mg. of sugar per 100 cc.; no organisms were found either by smear or on culture. A smear taken from a purpuric lesion was likewise negative. However, both blood and throat culture revealed Neisseria meningitidis.

Therapy was promptly instituted in the form of an infusion of 5% dextrose in isotonic sodium chloride solution containing 3 gm. of sulfadiazine sodium together with 5 cc. of adrenal cortex extract (eschatin®). An additional 15 cc. of cortex extract was administered both intramuscularly and intravenously, and penicillin was given intramuscularly every three hours in doses of 100,000 units of an aqueous solution.

During the first hospital day the patient's course was featured by the striking increase of the rash, which came to cover the entire body in the form of large purpuric lesions, and by the persistence of the state of shock. The blood pressure remained at 50 mm. of mercury systolic and 20 diastolic, and there was almost complete anuria, but 15 cc. of urine being obtained by catheter during this time. Administration of sodium sulfadiazine therefore was discontinued after a total of 4 gm. had been given. Cortical extract was continued in doses of 10 to 15 cc. in every 12 hr. but apparently was without effect; an infusion of 250 cc. of plasma conferred but transient benefit.

The subsequent administration of additional infusions of dextrose in isotonic sodium chloride solution, two injections of ephedrine, and the repeated administration of cortical extract were similarly without avail, and the condition of the patient deteriorated steadily during the second hospital day. The state of collapse was unrelieved, and anuria was complete, the nonprotein nitrogen level being 75 mg. per 100 cc. The sugar content of blood taken at this time was at the hypoglycemic level of 40 mg. per 100 cc. Toward the middle of this day all medication save penicillin was discontinued, and the patient appeared moribund.

At this time 37.5 mg. of cortisone was administered, to be followed at six hour intervals by two additional doses of equal size. Within four hours after the initial administration of cortisone the patient exhibited a remarkable degree of improvement. The blood pressure rose to 100 mm. of mercury systolic and 60 diastolic, the pulse became full and bounding, the color improved, and the patient excreted 150 cc. of urine. In the 6 hours following the blood pressure attained a level of 130/80 and subsequently did not fall below 100/70; the pulse rate fell to 110 a minute and remained full.

During the third hospital day the patient became alert and rational, though with severe pains and hyperesthesia in all the extremities. The cerebrospinal fluid at this time contained 31 mononuclear cells but was normal in other respects. The output of urine was normal, and the nonprotein nitrogen level had fallen to 48 mg. per 100 cc. An indwelling catheter which had been in place since admission was removed, and chloramphenicol (chloromycetin®) was administered at the rate of 1.5 gm. a day for the prophylaxis of urinary-tract infection.

In the days that followed the course continued favorable. The purpuric rash faded except in those areas on the extremities in which local necrosis, followed by sloughing, necessitated local treatment, and these cleared in turn. By the seventh hospital day the use of penicillin and chloramphenicol was discontinued. And on the 14th hospital day, after reexamination of the blood showed it to be normal in all respects, the patient was discharged as cured.

COMMENT AND SUMMARY

We have described the case of a child with fulminating meningococcic sepsis complicated by profound collapse, anuria, and hypoglycemia (the syndrome described by Waterhouse and Friderichsen). After the administration of dextrose in isotonic sodium chloride solution, plasma, and adrenal cortex extract had proved unavailing, the administration of cortisone was followed by dramatic recovery from the state of shock. This observation supports the hypothesis held by many, yet recently called into question, that adrenal damage plays a central role, together with acute sepsis, in the determination of the clinical picture of the syndrome.

Beyond this, the observation touches on the larger, vital questions concerning the nature of infectious stress and of the collapse which may attend it. Some evidence has been presented and more is at hand to show the impact of infection on the adrenal glands, and it is suggested that their exhaustion and the breakdown of their function may have a critical part in the outcome of severe or uncontrolled infections. The recent work of Finland [36] is of interest in this regard.

The nature of shock in these conditions appears to be different from that following trauma, hemorrhage, or even slowly developing adrenal insufficiency. It is not related simply to the diminution of blood volume. Neither has sufficient electrolyte imbalance been found in these cases, nor have blood, plasma, or salt solutions conferred significant benefit. Desoxycorticosterone, effective in the control of electrolyte distribution, has been of doubtful value and adrenal cortex extract of limited effect.

In the light of these considerations, it appears that when shock occurs in infectious diseases it may come about by a different mode of pathogenesis, possibly related to the profound effects of the 11, 17-oxysteroids on the surface of tissue cells and on the permeability of their membranes. The recent advances in our understanding of adrenal cortex physiology, culminating in the discovery of cortisone and its application to clinical medicine, introduce new elements into the situation, and it may now become possible both to elucidate the fundamental nature of these cases and vastly to improve their outcome.

---

ADDENDUM

Since the foregoing report was submitted for publication, one of us (J. N.) saw another case of the Waterhouse-Friderichsen syndrome successfully treated with cortisone (From the Medical Service, Dr. B. Pasquarelli, director, Fordham Hospital).

On Jan. 28, 1951, a 28 year old woman was admitted to the hospital with a one-day history of pain in the neck and back, vomiting, and increasing confusion. She was febrile and delirious. The neck was moderately stiff. The blood pressure was 130/70. The pulse rate was 110 a minute. Lumbar puncture revealed the spinal fluid to be under increased pressure with polymorphonuclear pleocytosis and gram-negative cocci which proved to be Neisseria meningitidis.

An infusion of isotonic sodium chloride, containing 4 gm. of sulfadiazine sodium, was given. In addition, one million units of penicillin was administered intravenously and intramuscularly, and 1 gm. of streptomycin was injected intramuscularly, as was 2 cc. of adrenal cortex extract (eschatin®). Further therapy consisted of 600,000 units of penicillin every three hours, 0.1 gm. of sulfadiazine every four hours, 2 cc. of adrenal cortex extract every six hours, and 0.5 gm. of streptomycin every 12 hours; later, the streptomycin was replaced by 100 mg. of aureomycin every six hours.

During the 24 hours following her admission, the patient's condition grew worse: signs of meningeal infection increased, the rash spread and assumed a universal, purpuric character, and the blood pressure declined to 80/50. The patient became comatose, was in collapse, and appeared moribund.

At this point, cortisone therapy was instituted, 100 mg. being administered intramuscularly every six hours. The patient began to exhibit a favorable response within a few hours and then improved steadily. The state of shock receded. The coma lessened. During the subsequent 12 to 18 hours of the second hospital day, the pulse became stronger and the blood pressure rose to 100/75.

On the third hospital day, the patient was oriented and reasonably alert. The blood pressure was maintained at normal levels. The rash began to fade. The urea-nitrogen level in the blood was 15 mg. per 100 cc. and the sugar 140 mg. per 100 cc. Many polymorphonuclear cells were still to be found in the cerebrospinal fluid, and its protein level was 360 mg. per 100 cc.; but the sugar was 58 mg. per 100 cc., and the fluid was sterile.

The administration of cortisone was discontinued when a total of 500 mg. had been given. The subsequent course was uneventful; after 10 days, the patient was discharged as cured.

535 Park Ave. (Dr. Nelson).

THE DETECTION OF PELVIC CANCER

Howard W. Jones Jr., M.D., Baltimore

Cancer of the genital organs accounted for 24.2% of all deaths due to cancer in females in 1947 in the United States.[1] The uterus is by far the most frequent site, uterine cancer accounting for 18.1% of the deaths. If cervical cancer accounts for approximately 80% of all uterine cancer, the deaths from cervical cancer alone may be estimated to make up about 14% of all deaths due to cancer in females. This is important when one considers that Stage I cancer of the cervix (as classified according to international agreement adopted at the International and Fourth American Congress on Obstetrics and Gynecology, New York, May, 1950) can be cured in 80% of all patients and international Stage 0 cancer in approximately 100%; yet the general survival rate from carcinoma of the cervix is in the neighborhood of 30%, because of a preponderance of advanced cases.

For many years, but with recently renewed vigor, organized effort has been made to educate the public and the profession in the early symptoms, diagnosis, and therapy of cancer. It seems reasonable that efforts in this field should be sustained by the American Cancer Society. It must be realized, however, that complete education of the public and profession would probably not result in discovery of all pelvic carcinomas in an early stage, for the biological behavior of the disease in many instances results in its insidious development. At the Cardiff Royal Infirmary, Cardiff, Wales, for example, more than one-half of all women seen within three months of the first symptom were classified as having Stage III or IV carcinoma of the cervix.[2] For this reason a periodic pelvic examination has been suggested as a means of diagnosing asymptomatic pelvic cancer. It is not the purpose of this paper to contrast the result of public and professional education with the value of periodic pelvic examination of asymptomatic women, but rather to assess the value of the latter in statistical terms and to comment on the adequacy of new and old procedure in the detection of asymptomatic pelvic cancer.

MATERIAL AND METHODS

The statistics are taken from results of 8,955 examinations of women in detection centers in Maryland that were sponsored by the Maryland Division of the American Cancer Society. These women were given a general examination, but only the pelvic findings are reported herein. The examinees were considered to be well. There is opportunity for debate on this point, as the line between illness and health is not sharp. Women with gross complaints were eliminated, and those admitted considered themselves well. However, in many instances expert questioning often revealed symptoms of pelvic disorders.

Although these were detection-center examinations, there is no reason to believe that the yield of abnormal findings would be less if adequate routine pelvic examinations were done on

patients who present themselves in physicians' offices with complaints referable to other parts of the body.

The pelvic portion of the examination consisted of history, inspection of the external genitalia, bimanual palpation, speculum examination of the cervix and vagina, biopsy of any available lesion, and cytological examination of material from the cervix and posterior fornix in about the last one-half of the series. A wooden spatula was used for the smear. The examinations were done between Nov. 1, 1946, and Feb. 28, 1950.

In order to assess the value of a detection examination and in order to determine the supplementary yield of cancer diagnosis from additional procedures recommended on the detection examination, an attempt has been made to follow a sample of the examinees. Of 10,111 male and female examinees 5,353 were followed. This included about one-half of the 8,955 female examinees reported on herein. Well examinees were followed six months after examination and those with abnormalities two months after examination. Sixty-two per cent of all examinees were successfully contacted by mail. In presenting the findings, a distinction has been made between the diagnoses on the detection examination per se and the supplementary diagnoses made by means of procedures carried out by the examinees' physicians. The latter group was revealed by the follow-up study and is, therefore, incomplete.

As will be indicated below, the follow-up also served to point out the limitations of the detection examination.

RESULTS

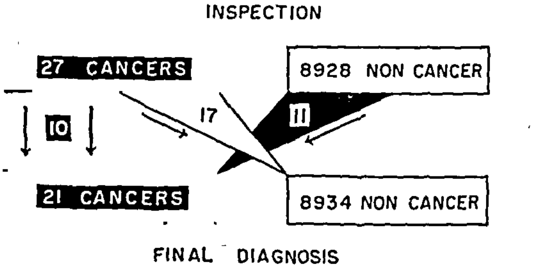
General.—Of the 8,955 examinees, 2,444, or 27.3%, were noted to have at least one positive abnormal finding in the pelvic. The examinees are classified in Table 1 as having cancer, major benign pelvic condition, minor benign pelvic condition, or no pelvic abnormality. A major benign pelvic condition implies a possible indication for a laparotomy or major vaginal procedure, while a minor benign condition implies a possible indication for a dilation and curettage, cauterization of the cervix, an office procedure, or the like.

Table 2 shows the abnormal conditions in the 2,444 persons with positive pelvic findings. The total abnormalities are greater than the number of patients, as 35% of those with positive pelvic signs had more than one abnormality. It should be noted that in this table the mere presence of an abnormality is not an accurate indication of its importance. The therapeutic or diagnostic procedures advised are a more accurate indication of a lesion's importance, and these are shown in Table 3. If no therapy was recommended for a disorder, the patient's general condition was such that treatment was not warranted (30 instances), the lesion was considered to be inconsequential, or active therapy was not indicated, as for an asymptomatic myoma.

External Genitalia.—In the United States there were 430 deaths due to vulvar carcinoma in 1947.[1] This death rate of 0.6 per 100,000 for all ages ranks next to that for vaginal carcinoma in infrequency.

No carcinoma of the vulva was found among the examinees.

The 41 examinees with leucoplakia of the vulva represent an important by-product of the examination as potential carcinoma patients. No important lesion of the vulva was uncovered in the followed group.



Value of inspection in diagnosis of cervical cancer.

Cervix.—Twenty-one examinees were noted to have cervical carcinomas. The condition of 17 of these was conclusively diagnosed at the detection center. In the remaining four cases conclusive diagnoses were made by the examinees' private physicians as a result of procedures suggested by the detection center examiners.

There were two International Stage III, three Stage II, 12 Stage I, and four Stage 0 lesions.

The discovery of two Stage III lesions in asymptomatic women serves to emphasize the importance of periodic pelvic examinations, as well as the complexity of the problem of public education.

All were epidermoid carcinomas except one Stage I adenocarcinoma.

The examiner expressed a clinical suspicion of carcinoma in only 10 of the 21 cases of proved cervical cancer. Carcinoma was *not* seriously suspected in the remaining 11. In addition to this, there were 17 other cases in which the examiner's note indicated that an early carcinoma was suspected, but in which the biopsy specimen showed no abnormality. In short, inspection, although important, is an unreliable diagnostic method for early carcinoma of the cervix (Figure). When pelvic examinations are made for this purpose, the examiner must be prepared to use other diagnostic aids.

Of special interest has been the frequent use of biopsy of the cervix, not as a method of confirming a diagnosis that can be made by inspection, but as an active aid in the diagnosis of early cancer of the cervix. Of the 8,955 examinees, 3,819, or 43%, had a biopsy. Some of these specimens were taken in one center where a biopsy of the cervix is a routine clinical research procedure.

It can probably be said that in our series no carcinoma has been found in a cervix that could be considered absolutely normal in every respect, although many have been discovered in cervixes with minimal abnormalities. Table 4 shows the results of biopsy. Follow-up of patients with basal-cell hyperplasia is most important.

The publication by Papanicolaou and Traut [3] in 1943 of their monograph on the diagnosis of uterine cancer by the vaginal smear has resulted in widespread use of and interest in this method of diagnosis. It has now been established as an accurate and useful diagnostic tool. According to Papanicolaou,[4] a staff consisting of two technicians, a secretary, and a pathologist is ideal for the examination of slides from 25 patients per day. It, therefore, becomes necessary to inquire whether a smear study will lead to the diagnosis of a substantial number of carcinomas that would be missed by standard diagnostic methods, including biopsy.

Table 4.—*Results of Biopsy (Detection-Center Specimen)*

	Number	% with Biopsy, Cervixes
Normal	1,221	32.0
Cancer	17	0.4
Cervicitis	2,513	65.8
Basal-cell hyperplasia	16	0.4
Not taken	5,136	....
Unsatisfactory	52	1.4
Total	8,955	....

Of the 21 persons with proved carcinomas of the cervix, only nine had a cervical and vaginal smear. Of these, one had Class II, five had Class III, and only three had Class IV smears.

Of the women with benign or normal cervical conditions, 4,138 had cervical and vaginal smears. Of these, 3,922 had Class I or II, 88 had Class III, and six had Class IV smears (Table 5).

All women with Class III and IV smears have had at least one negative biopsy specimen. Ten of these have had negative dilation and curettage. It is only fair to say that there may be a yet unproved carcinoma among the 102 with Class III and IV smears. Further follow-up of this group is most important.

Table 6 attempts to correlate the smear findings with the biopsy results.

Although the literature contains reports of patients with positive smears and negative biopsy specimens in whom a diagnosis of cancer was subsequently made, there has not been such a patient in this series.

Of special interest were the clues that led to the diagnosis of the four carcinomas in the examinees who had further procedures by their private physicians. Two of these examinees were seen early in the detection-center experience and presented menorrhagia, as well as abnormal cervixes. Biopsies and curettages were recommended and carried out by the private physician in each instance. At present each of these would doubtless have had both a smear study and a biopsy at the detection examination. The third patient had a cervical polyp removed at the time a Class III smear was obtained.

Table 5.—*Smear Findings (Detection-Center Specimen)*

Class	Number	% Cases with Smears
I	250	6.0
II	3,672	88.5
III	93	2.3
IV	9	0.2
V	0	0
Not taken	4,809	...
Unsatisfactory	122	3.0
Total	8,955	...

Because of the Class III smear, performance of a biopsy, which should have been done at the center, was suggested to the private physician. This was done by the examinee's physician and showed an intraepithelial carcinoma. The fourth patient had a Class II smear and a biopsy speciment showing basal-cell hyperplasia. Because of this, a repeat smear and biopsy specimen were obtained by her private physician. The smear was considered unsatisfactory, but the repeat biopsy specimen showed unmistakable intraepithelial carcinoma.

On the basis of experience with the present series, it may be said that one carcinoma would have been missed if biopsy had been reserved for Class III and higher smears. On the other hand, one Class III smear led to the biopsy of a cervix that was disregarded at the original examination.

There can be little doubt that the routine use of a smear study plus biopsy of abnormal cervixes results in the most comprehensive detection examination. However, smears are even now not generally available, and it is important to emphasize that in our series the smear method has not added statistically to the yield of cervical cancer. In short, it might be said that one can be a competent gynecologist even in the diagnosis of early carcinoma of the cervix without the benefit of a cytological service, provided there is no hesitancy in taking an adequate biopsy specimen of all abnormal-appearing cervixes.

Table 6.—*Results of Smear Study Plus Biopsy (Detection-Center Specimen)*

Results of Biopsy Class of Smear	Not Taken	Normal	Carcinoma	Cervicitis	Basal Hyperplasia	Unsatisfactory	Total
I	141	59	0	49	0	1	250

Not taken	2,890	715	10	1,163	4	27	4,809
Unsatisfactory	60	12	0	49	1	0	122
Total	5,136	1,221	17	2,513	16	43	9

This discussion should not be interpreted as a criticism of the value of the smear as a dependable tool for a single method of screening the population, as used by Kraushaar, Bradberry, and Brown,[5] or Nieburg and Pund,[6] or as a criticism of its accuracy, which has been demonstrated in publications by Isbell, Jewett, Allan, and Hertig,[7] Scheffey, Rakoff, and Hoffman,[8] and in other studies, including the present report. However, when evaluated as an adjunct to the routine methods of pelvic examination, it becomes a less important procedure.

[4] Papanicolaou, G.: Personal communication to the author.

In view of the fact that study of a smear will sometimes reveal a carcinoma undetectable by biopsy, its routine use as part of a completely perfect detection examination is an ideal situation. It is clear that either a smear study or a biopsy of all abnormal cervixes must be done in any adequate detection examination.

It is interesting to note that the number of carcinomas of the cervix detected is about twice the expected incidence. In Table 7 the incidence rate is calculated from the data of Sadugar and Palmer.[9] This may indicate that an adequate detection examination will reveal most carcinomas that are destined to become symptomatic within the next two years or more. However, the possibility that the detection-center population is selected cannot be disregarded.[10]

Table 7.—*Cervical-Cancer Expectancy Among 8,955 Examinees, Based on Data of Sadugar and Palmer*[9]

Age	No. of Examinees	Incidence Rate per 100,000	Expectancy Cases
0-19	54	0	0

30-39	2,883	6.6	1.89
40-49	2,654	13.7	3.63
50-59	1,495	18.8	2.89
60-69	479	16.1	0.77
70-over	100	8.5	0.09
Unknown	7	...	....
Total	8,955	...	9.40

That an adequate detection examination implies the study of a smear or biopsy is emphasized by the follow-up study. One examinee who was considered well had clinical carcinoma of the cervix about six months after the detection examination. She was seen in the early part of the study and had neither a smear nor a biopsy specimen taken. It is possible, but in our opinion not probable, that this patient's condition was not detectable when she was seen.

Carcinoma of the Fundus.—In 1947 the death rate for carcinoma of the uterus in the United States was 24.1 per 100,000.[1] The incidence rate is obviously higher. Dorn[11] gives it as 54 per 100,000. If the ratio of deaths due to carcinoma of the fundus to total deaths due to uterine cancer is taken as 1 to 5, the incidence rate for carcinoma of the fundus must be about 10 in 100,000 for all ages. This means about 10,000 examinations for one fundal carcinoma, or somewhat fewer if the age factor is considered. Carcinoma of the fundus is not a detectable lesion by routine methods. It should be the field of greatest usefulness for the vaginal smear. Among the 8,955 examinees, two cancers of the fundus were found by curettage. These patients had a history of menometrorrhagia. At that time no smears were being taken. In 10 other patients dilation and curettage was done because of positive smears and negative cervical biopsy specimens, but to date no carcinoma of the fundus has been detected by this procedure.

If a smear is to be used as a diagnostic method for fundal carcinoma, one must be prepared to examine up to 10,000 smears from asymptomatic women for one positive case.

Ovary.—The ovary is second only to uterus as a site for fatal pelvic cancer. In 1947 carcinoma of the ovary accounted for 5.2% of all deaths due to cancer in females, with a rate of 7.0 per 100,000.[1] Among the 8,955 examinees, 109 had adnexal masses. Only 16 of these are known to have come to operation. The actual figure is probably higher, but in many instances at a subsequent examination the mass was found to have disappeared. Not one case of carcinoma of the ovary was found in the patients operated upon.

On the other hand, two women who did not have palpable adnexal masses and were considered well at examination had fatal ovarian cancer within six months. It must be concluded that the yield of operable ovarian cancers among asymptomatic women is very low and that fatal malignant ovarian growths may develop in spite of periodic pelvic examinations.

CONCLUSIONS

Cancer of the cervix is detectable in asymptomatic women by routine examination, provided biopsy and/or smear study of all abnormal cervixes is a part of the examination. Inspection alone is not a reliable diagnostic method for small carcinomas of the cervix.

In the experience reported on, with the use of an examination that includes biopsy of abnormal cervixes, the smear has not added statistically to the yield of detected cervical carcinomas. Both the smear study and the first biopsy may be considered to have missed one of the 21 cervical cancers found.

An ideal detection examination consists of smear study and biopsy of abnormal cervixes, in addition to history-taking inspection, and palpation. Any woman who has such an ideal detection examination with no abnormal findings may be reasonably sure that no clinically important cervical cancer will develop within six months, and perhaps longer.

Carcinomas of the fundus and ovary are seldom detectable in asymptomatic women, although the further investigation of minimal symptoms may result in the prompt diagnosis of lesions.

ABSTRACT OF DISCUSSION

Dr. Herbert F. Traut, San Francisco: If there be any criticism of the methods, it probably can be directed only toward the follow-up. The assumption that cancer of the uterus does not exist after a single routine pelvic examination, augmented by biopsy and study of a vaginal smear, is not quite warranted. We do not yet know the exact value to place on such examinations. We know that negative findings are not as reliable as positive ones, but how many negative biopsy specimens or how many negative vaginal smears are necessary in order to rule out the presence of cancer has never been established. Follow-up by mailed questionnaires is not as satisfactory as one could wish, nor can the results as quoted by referring physicians be accepted in the same category as those made by an expert working in this field. The author concludes that the best possible procedure for revealing cancer of the uterus is a combination of the vaginal-smear study and biopsy. In this we are inclined to agree with him wholeheartedly. He says that the biopsy method alone has been found to be as reliable as the vaginal smear alone. With this we cannot agree, particularly in regard to the very early lesion. The biopsy method, as applied to the problem of cancer of the uterus and its therapy has been on trial and has been found wanting. The specialized cancer-detection center is an experimental phase that must be passed through. Thus far, we have found it to be an extraordinarily expensive means of discovering ovarian and uterine cancer in women. But ovarian and uterine cancer represents somewhat less than a third of the cancers to which women are heir. We must look through the low-power magnification rather than the high-power—look at the woman more as a whole than as a gynecologic patient, for half of her cancers will arise in the gastrointestinal tract, approximately one-fourth in the breast, and approximately one-fourth in the genital tract. The cancer-detection center should be a chronic-disease detection center and should be located in the local physician's office; the profession as a whole should be trained to this concept and be made competent to carry out the procedures that would reveal these various diseases. The laity must be taught that their health is as important as anything else they possess and that they must place themselves in the hands of their local physician at reasonable intervals—we suggest six months for parous women and twelve months for nulliparae—for the purpose of a general health examination, which would include, of course, the various examinations necessary for detecting cancer. The biopsy method of cancer diagnosis and the procedures of cytological nature, such as study of vaginal or cervical smears, constitute a somewhat expensive, skilled, demanding technic. Neither method is going to be satisfactory unless it is carried out in laboratories of high caliber, with good technicians and good diagnosticians. These must be made available, and to assume that they are available for the diagnosis of biopsy specimens is an inaccuracy. It will be some time before considerable numbers of diagnosticians will be available, but they are becoming available at a rapid rate, and the time will soon be here when all who need them may have the benefit of these two methods of cancer diagnosis under the best possible auspices. We would differ with the essayist as regards cancer of the fundus. The fact that he had only two instances of cancer of the fundus in his whole series is remarkable. That neither of these was found by vaginal smears would seem to indicate some fault in the technic or the experience in diagnosis.

Dr. Frederick H. Falls, River Forest, Ill.: The diagnosis of carcinoma of the uterus in a detection center is extremely important, but I believe detection centers are not the last word in finding carcinomas of the uterus and that the emphasis should be placed on the detection of carcinoma of the uterus in the physician's office. The cervical-smear reading is a technical feat that is not too difficult for ordinary technicians. It is up to the physicians to provide in each community a trained technician who can read these smears, and to assure in all cases in which suspicion of a carcinoma is aroused that smears are taken and submitted for examination. Soon after the Papanicolaou smear began to be applied to the diagnosis of carcinoma, I sent a man to work with Papanicolaou. After three weeks he returned, and we agreed to have him examine by smear all cases in which from the clinical standpoint we felt there was a carcinoma of the uterus. We did hysterectomies on these women. We found that whenever we felt clinically there was a malignant growth in a uterus the smear backed us up. That gave us faith in the smear method for diagnosis of uterine carcinoma. There is one condition that sometimes obviates the value of a smear, and that occurs in women past the menopause who have cervical strictures. Cervical strictures retain cells shed from the upper part of the cervix and the body of the uterus, and a carcinoma may be present for some time before its erosion destroys the cervix sufficiently to allow blood and discharge to come down into the vagina and be shown on clinical smear or by clinical symptoms. Therefore, in routine pelvic examinations, it is our custom to perform the so-called Clark test, in which a probe is passed through the cervix into the uterus. First, this procedure determines definitely that the cervix is patulous; secondly, if there is a lesion in the upper uterine tract, an abnormal amount of bleeding is caused by the invasion of the cavity with the probe. The vaginal smear in some cases may be positive in the presence of negative cervical and endometrial biopsy specimens. We have had two instances of this apparent paradox and in each case have found a carcinoma of the Fallopian tube. A negative biopsy report does not mean that there is no carcinoma in the cervix. We have seen positive and negative carcinoma sections obtained from the same block of biopsy material. The pathologist, therefore, is limited in his ability to help with the diagnosis of carcinoma by the sections that are presented to him for study.

Dr. Howard W. Jones Jr., Baltimore: I had requested that Dr. Traut be included as a discussant because I felt sure he would be the leader of the opposition. One of the discussants commented on the fact that the biopsy had been advocated for years and had been found wanting. I quite agree with him that the greatest advantage of a smear is that it is easy to take. I cannot agree that the biopsy is any less accurate than the smear study, particularly since one has to take into consideration the fact that there are some false leads from the smear. For example, in the nine cases of carcinomas that occurred in our smear era, only three showed Class IV smears, while at the same time there were six cases of Class IV smears in which repeated biopsies, smears, and dilations and curettages did not reveal the presence of carcinoma. If that is due to inexperience or difficulty in technique, it is because the average technician and the average cytologist cannot master the method, and, if the technique is too difficult to master, it is no good. The comment about the fundus is interesting, because if one estimates the incidence of fundal carcinoma in this series it turns out that there should have been exactly two cases of carcinoma of the fundus, which, in fact, was the number found. Therefore, I can make the same comment about carcinoma of the fundus as I can about that of the ovary, namely, that with current diagnostic methods the routine periodic pelvic examination is not a particularly valuable procedure. However, for detection of carcinoma of the cervix it is very valuable.

On the Road to a Life Worth Living.—Spectatorism is not much more than glorified idleness, whether it be at picture shows, athletic shows, or video. . . . *Activity,* planning, and ambition for leisure time leads to development of all the best potentialities of the individual; and achievement of success in the pursuits of one's own free choice is the source of true happiness. . . . There is one sure way to prevent frustration: it is substituting attainment for entertainment. It takes determination, enthusiasm, and civic, artistic and religious idealism to get the child started on the road to a life worth living.—Karl E. Kassowitz, M.D., Self-Expression and Self-Discipline: The Dualism in Education, *Wisconsin Medical Journal,* February 1951.

RESECTION OF VESICAL NECK IN CHILDREN

INDICATIONS AND RESULTS

T. Leon Howard, M.D.
and
Henry A. Buchtel, M.D., Denver

The development of children's urology was hampered by two totally different factors. The first, purely mechanical, was overcome by the fabrication of proper instruments, and the second and more important factor, the psychologic, was overcome by the realization of physicians that children do have urologic complaints for which proper diagnosis can be made and treatment given. Dr. Meredith Campbell's textbook "Pediatric Urology"[1] helped make many realize the psychologic importance of urologic disease in children.

The average physician is quite used to the patient with disease of the urinary tract who directs his complaints toward that field and is able to cooperate in simple examinations. The average urologist is also accustomed to a patient who has large veins and an adequate urethra and who can urinate at will. The child, on the other hand, frequently has small veins, urethral inadequacy, and inability to urinate at will. His symptoms may not be urinary, and collection of a specimen for urinalysis may be difficult. An excretory urogram may involve great physical and mental travail, and cystoscopy may be impossible without induction of general anesthesia, and perhaps then only after perineal urethrotomy. Because of these difficulties, the diagnosis in children is often wrong, and the child may be treated for years incorrectly.

A well equipped, well staffed hospital, such as the Children's Hospital, Denver, is of great value in solving the problems of pediatric urology.

The urologist's emphasis on the importance of early diagnosis will help the pediatrician toward earlier recognition of urologic disorders and will aid him in seeking proper treatment. The pediatrician's early diagnosis of urinary infection and the radiologist's demonstration of urinary retention are of little benefit, however, if the urologist's only treatment is administration of a new and different urinary antiseptic. Children's instruments are not an expensive addition to the urologist's armamentarium when one considers the satisfaction in preventing further urinary tract destruction in even one patient.

One more prejudice must be overcome: the theory that young children do not stand examinations or operative procedures well. This is entirely false, for children seem to have less reaction to the organic iodides than adults have and they rarely show any reaction to cystoscopy. Naturally, for long procedures an infant must be supported by intravenous therapy, or better by transfusion, but support is seldom necessary for operative cystoscopy. Cystoscopy, if indicated, can be done at any age. Ordinarily, the infant female urethra will accommodate the average child's cystoscopy, and the instrument can usually be introduced through the perineum in the baby boy. If this is impossible, the presence of an indwelling catheter for several days makes instrumentation possible. This fact we have proved on many occasions.

The lack of proper resectoscopes has been a major hindrance to the development of children's urology. A child's resectoscope, the Thompson, has been available only a decade, and many urologists refused to use it because of the visual system. Since recently a child's resectoscope with the familiar lens system was evolved and since many urologists are purchasing this, we thought an analysis of our patients seen since 1945 would prove valuable.

CLINICAL MATERIAL

The clinical material consists of 104 patients up to 14 years of age. Of these, 41 had resection of the vesical neck, and they are compared with 63 who had only dilation of the urethra. We have excluded from the group of resections those done for a frankly neurogenic bladder, and one which was done inadvertently on a patient with recurrent urinary infection due to obstruction in the lower ureter. In the series with dilation we have retained only patients thought to have contracture of the bladder neck. This excludes many patients with enuresis who were treated with fulguration of inflammatory areas, as well as those who were believed to have urethritis alone.

Dilation.—Our small series reveals little about age groups in general except to show at what age we are asked to see patients (table 2). It might be used for comparison with other areas to see whether the pediatricians are prompt in asking for consultation.

The largest amount of residual urine in this group was 140 cc. in a girl. Another girl with 120 cc. was the sister of a girl in the resection group. The one miscellaneous symptom was pain over the right kidney in a girl 6 years old. She proved to have slight caliectasis on the right, but a good result was obtained by bladder neck dilation. The damage was listed as slight, and there never was an increase in the nonprotein nitrogen. The one patient with reflux was a girl 5 years old who also had trabeculation of the bladder and slight dilatation of the upper urinary tract. These would be valid signs for resection, but the girl stayed clinically well after dilation, and the mother would not bring her in for further study. We have listed her among those with good results, for she has remained well more than two years, but of course we may have to place her in a different category in the future.

Results of Dilation.—Of these patients 49, or 77.78 per cent, have stayed well without the necessity of further treatments. (This result is not so good as it might appear, as 15 patients who were originally treated by dilation subsequently underwent resection; therefore, data on them do not appear in this table.) The other 14, or 22.22 per cent, have had further difficulties that required additional treatment, including repeated dilations in five. The records indicate clearly that two of these

Read before the Section on Urology at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 28, 1950.

[1] Campbell, M. F.: Pediatric Urology, New York, The Macmillan Company, 1937.

patients need bladder neck resection, and probably the others do, too, in spite of the normal appearance of the bladder neck. Included in this group are four patients who had fulguration of the bladder neck as well as dilation. Although fulguration was done an additional five times, these patients eventually were subjected to resection. Sphincterotomy was done on a boy who also underwent resection. In other words, children with abnormal-appearing bladder necks seldom are permanently benefited except by resection.

Resection.—The age group distribution (table 4) again shows when the patients were sent to us for consultation. The number of boys over 11 years old is unusual. In two of these the symptoms had been present a long time, and marked upper urinary tract damage was present. In the other two, symptoms apparently developed at puberty. The urologic disorder of a 1 year old boy was accidentally discovered by a good diagnostician who saw the child because he had anemia. Further study revealed severe damage of the urinary tract with infection and elevation of the nonprotein nitrogen level. Fortunately a good result was obtained by resection. The cases of the two girls 1 year of age will be discussed in greater detail later.

Table 1.—*Sex Distribution*

	Resection		Dilation	
	No.	%	No.	%
Boys	16	39.02	9	14.29
Girls	25	60.98	54	85.71
Total	41		63

Comparison of the percentages of signs and symptoms in these patients (table 5) with those given in table 3 reveals a striking difference. The miscellaneous symptoms consisted of anemia (probably a sign) in one patient and pain over the right kidney in a boy 13 years old; however, he had no demonstrable reflux or damage to the kidney. It is unfortunate that 33 patients had residual urine and 33 urinary infection, for this is not an identical group, as six patients with residual urine had no urinary infection and three of these had never had symptoms of urinary infection. Similarly, the group with a history of urinary infection and that with the finding of urinary infection are not as identical as the close numbers might indicate, for patients with a history of infection came to us with sterile urine and others without definite history of chills, fever and pyuria came to us with an infected urine.

This may seem a minor point, but we wish to emphasize the fact that all patients with urinary infection do not necessarily show comparable symptoms and that patients with residual urine and enough involvement of the bladder neck to justify resection can be relieved by treatment with modern urinary antiseptics. Frequently, it is the custom to call in the urologist only when urinary infection persists in spite of therapy or recurs frequently.

Table 3.—*Symptoms and Signs in Sixty-Three Patients with Dilation*

Enuresis	3	.....	Trabeculation	9	14.29
Enuresis and frequency or incontinence during the day	7	.....			
Miscellaneous	1	.....			

An illustrative case is that of a boy 4 years old who had had a serious urinary infection a year before we saw him. At that time he was cared for by a capable urologist who inserted an indwelling catheter and informed the family that the boy did not empty his bladder. However, he made no roentgenographic studies, nor did he suggest that anything be done about the residual urine. Since the boy had been well for a year without any medication, we suggested that there could be nothing seriously wrong. However, our studies showed pyelectasis and ureterectasis on the right and multiple diverticula, including one large diverticulum with an orifice near the right ureteral meatus. There was no reflux, and we believed the obstruction to the right ureter was secondary to the diverticulum. The bladder neck was resected, and after this the boy emptied his bladder. Soon after this he left Denver. Our hope that the kidney would improve was not justified, as recently nephroureterectomy was done.

We tend to forget the efficacy of modern urinary antiseptics, and that a child's recovery from a urinary infection with no recurrence for a year does not preclude the existence of serious obstructive lesions of the urinary tract. Improvement following dilation with later recurrence of symptoms is not an infallible indication that resection should be done; nor, on the other hand, is failure to improve a sign that resection should not be done.

Results of Resection.—The results were poor in 13 of the 41 patients (31.7 per cent) with resection. Two children, one boy and one girl, died. Both had serious damage to the upper urinary tract. Both did poorly after resection. The nonprotein nitrogen continued to rise, and physical development was faulty. Suprapubic tubes were inserted in both children; a nephrostomy was performed in one, and both died of renal failure. Among those with poor results we have included two boys with damaged upper urinary tracts and a permanent increase in the nonprotein nitrogen. Their conditions were quite similar, and a description of one will be presented later. One boy had a urethral stricture similar to that seen in adults

following resection; three have had repeated urinary infections, and two girls still complain of urinary difficulty. In one we can see no reason for this; the other has dysuria when she is constipated. More than one resection has been done in five, four of whom have already been mentioned.One boy had such severe urinary tract damage that suprapubic drainage was indicated. Three months later resection was performed, and since then the boy has done well. However, we still dilate the urethra under anesthesia from time to time, and, therefore, he is included in this group with poor results. One girl who had undergone resection previously elsewhere still had residual urine and urinary infection. We performed resection with the same results, and she is now under the care of a third urologist. The remaining 28 patients, or 68.29 per cent, have remained well.

Let us warn you of one pitfall in following children who have had resection. A child with a thickened bladder wall and a damaged upper urinary tract with reflux can void into his kidneys as easily as and sometimes more easily than through the urethra. Therefore, checks of the residual urine in this type of patient are worthless, as increasing renal damage can and does occur, in spite of the fact that the bladder is emptied by urination. Frequent estimation of the blood urea nitrogen must be done for such children to be certain that the improvement is real. This point is well illustrated by the case of the boy who died, for, in spite of the fact that he had no residual urine, damage to the upper tract was progressive.

Table 5.—*Symptoms and Signs in Forty-One Patients with Resection*

DIAGNOSTIC AIDS

When complete urologic investigation is necessary, we feel an excretory urogram should be done, and the films reviewed by the urologist. Of course, this approach is not always feasible. But in our experience attempts to proceed without urography have frequently resulted in poor diagnosis and treatment. We cannot stress too much the value of the excretory urogram in the management of children.

The method we use to check the presence of residual urine has certain advantages in children who may not be able to void at the desire of the physician. When such is the case, or at any time that there is a question whether residual urine exists, 1 ounce (29 cc.) of sterile liquid petrolatum is introduced into the bladder and the child is catheterized the following day. If liquid petrolatum is present, it is proof that the child has not emptied the bladder completely since the substance was introduced. The same method can be used for adults if desired.

The cystogram, and especially the cystogram made with the patient straining, is of great value in the management of bladder neck obstruction. The examinations that are not used frequently eough are urethrography and pyeloscopy. The former should be a routine procedure in dealing with bladder neck obstruction, and the latter a routine when the causation of ureterectasis is in doubt.

Cystoscopy remains one of the best diagnostic procedures. This can be done with local anesthesia if the child is well behaved. However, it is usually best done with the child under general anesthesia if there is a question of bladder neck obstruction, for it may be necessary to dilate the urethra, to view the bladder neck through different instruments and finally to resect if necessary. This can all be done under the same anesthetic. Our present practice is to start with the McCarthy miniature cystoscope, but, since this instrument at times (especially in the female) gives a poor view of the urethra, we frequently use other instruments. If the symptoms or signs indicate that resection is needed, the resectoscope is introduced. If after all this we are convinced that there is no obstructing tissue, the urethra is dilated with nos. 14 to 22 French catheters, depending on the size of the child. If bleeding follows this, an indwelling catheter is inserted for 24 hours. Should resection be decided on, this is done, and again a catheter is introduced for 24 hours. We find the nos. 12 and 14 Bardex catheters valuable for this. At the end of 24 hours the catheter is removed. In most instances the child voids properly and can be released from the hospital the following day.

REFLUX

The importance of reflux is shown by the fact that in our series only one child with reflux has not had bladder neck resection. In other words, the presence of reflux with bladder neck contracture is good evidence that resection should be done. However, two unusual types of reflux must be taken into account.

A young woman had a normal ureter and an obstruction at the ureteropelvic juncture. At operation nephrectomy was thought to be the treatment of choice. The ureter was tied with no. 1 chromic suture. The woman made an uneventful convalescence until six weeks later, when she was watching a ball game and drinking beer. Suddenly, she felt a severe pain in her right loin, and at surgery she was found to have the right retroperitoneal space full of urine from the stump of the ureter. The space was drained; the ureter retied, this time with silk, and she has had no further trouble. Obviously, this was reflux from bladder overdistention, which we know is not supposed to occur, but certainly did in this patient.

A child 6 months old had a functionless left kidney and a a normal right kidney according to excretory urography. The bladder and bladder neck were normal and only the left ureter was catheterized without difficulty while the child was under general anesthesia. However, the left ureterogram showed atresia of the upper ureter and reflux up the right ureter, with no overdistention of the bladder. A cystogram made on the child after he was awake showed no reflux. The condition of the child did not improve with dilation, and after the demonstration of reflux on straining, resection was done.

Naturally, this case belongs to a rare group. To demonstrate reflux we fill the bladder a reasonable amount and then have the child strain (if he is not already doing so) as though he were attempting to void.

A third type of reflux may occur because of abnormal ureteral peristalsis.

URETHRAL VALVES

We see little point in classifying various types of folds in the prostatic urethra as valves if the bladder neck must be resected to remove these folds. Instead, we prefer to include these in the total picture of contracture of the vesical neck. With this concept, there was but one patient who had a urethral valve. A 5 year old boy with enuresis, he was such a behavior problem that he was under a psychiatrist's care. After some time it was discovered that he had residual urine, and he was referred to us for cystoscopy, which showed a fibrous structure partially obstructing the prostatic urethra. This was engaged by the resectoscope with some difficulty, as it tended to wave back and forth, but once engaged it was excised. Aside from that nothing was done. The patient made a perfect recovery and has had neither urologic nor psychiatric troubles since.

UPPER URINARY TRACT DAMAGE

The damage to the upper urinary tract in this series ranged from none to irreparable destruction. A girl showed very slight damage represented by moderate pyelectasis and caliectasis. Dilation was first done at 6 years of age, but the patient was not relieved of her urinary infection, so resection was performed at the age of 10. After this the patient had no further urinary disturbance, but the mother insisted that the pyelograms be repeated until we considered the upper tract normal. It took 18 months for even this slight damage to be corrected, which should make us wary in predicting the disappearance of dilatation. Incidentally, this patient was the only one with an unusual pathological report on the tissue removed.

RESECTION OF APPARENTLY NORMAL BLADDER NECK

Resection in children when the bladder neck appears normal is a difficult problem. We wish to describe two examples of this. The first child presented an extremely stubborn condition.

The girl was first seen because of pyuria when she was 2½ years old. The child had a congenital dislocation of the hip, as well as a psychiatric behavior problem. She also took insufficient amounts of food and liquids for normal maintenance. At the original cystoscopy a suggestion that the bladder neck might be tight was entertained, but at all subsequent cystoscopies, and there were many, it was deemed entirely normal. After the original cystoscopy and pyelogram, the child made an uneventful recovery and her psychologic problem never recurred; but she had multiple recurrent urinary infections that were thought to be primarily in the left kidney.

Finally, on March 11, 1948, she entered the hospital with Pseudomonas bacteremia, with a similar organism in the urine, and was given streptomycin and sulfathiazole. During a hospital stay of 138 days she received a variety of urinary antiseptics, among them streptomycin, which at that time was considered the best for eradication of Pseudomonas aeruginosa. On June 4 treatment with mandelic acid was begun, and she had continued improvement until the mandelic acid therapy was stopped on June 26. On July 2, her temperature was 106 F. and the urine contained Staphylococcus pyogenes var. aureus and Escherichia coli. A no. 16 Foley catheter was placed in the bladder for continuous drainage, and her temperature came down satisfactorily. On July 13 the bladder neck was resected, and her course from then on was uneventful. She has remained well now for two years.

A boy 7 years of age when first seen complained of frequency and nocturia but had a negative urinalysis. On watching him void it was seen he had a weak dribbling stream, and by catheter he had 2 ounces (59 cc.) of residual urine. The excretory urogram was normal, but the cystogram showed slight reflux up the right ureter. The ureter appeared normal however. At cystoscopy, the bladder was not trabeculated and the bladder neck appeared entirely normal, so he was examined by a capable neurologist, who could find no neurological disturbance. Since his condition was unimproved by cystoscopy and dilation of the urethra to no. 16 French, the bladder neck was resected, with immediate relief of all urinary symptoms.

Such patients are not very common, but these examples are presented to show that bladder neck obstruction does exist at times in normal-appearing sphincters. In such cases the urologist should respect the bladder neck, in spite of the normal appearance.

The following case is that of one of the children over 11 years of age with unsatisfactory results.

This patient was first seen in November 1946 when he was 12 years of age, at which time his nonprotein nitrogen was 73.2 mg. per 100 cc., with a definite contraction of the bladder neck. When it was resected, Nov. 23, 1946, he had 500 cc. of residual urine. After this, he did well and the nonprotein nitrogen decreased to 42 mg. per 100 cc. of blood. In June 1947, the residual had increased to 5 ounces (148 cc.) and nonprotein nitrogen had increased to 60 mg. per 100 cc. Therefore, on June 25, 1947 additional tissue was removed. He improved, and in January 1948 the nonprotein nitrogen was 48 mg. per 100 cc. of blood. He left town and did not return to see us until October 1949, at which time he again had 5 ounces of residual urine and a nonprotein nitrogen of 92.5 mg. per 100 cc. of blood. His mother was written that further resection was indicated. In spite of this abnormal nonprotein nitrogen level the boy had developed normally, feels quite well and has no special complaints of any kind. We are certain that he has permanent kidney damage. It is quite remarkable to us that he empties his bladder at all, as the expulsive force is extremely poor.

BEHAVIOR PROBLEMS

It has been mentioned in the discussion on several of the patients that they were under he care of a psychiatrist, and many more in the group had definite psychologic problems. Without exception, when the urethra was dilated, these improved and in most cases were permanently relieved. We do not wish to convey the impression that all child personality problems are a result of bladder neck dysfunction, but we do wish to call attention to this possibility and to stress the desirability of examination of the urine.

BILATERAL URETEROCELES

In one of the patients with a poor result following resection because of recurrent urinary infection, the original urinary difficulties were due to bilateral ureteroceles, which were opened in January 1946. The boy did well until the summer of 1948, when there was recurrent urinary infection. On cystoscopy the ureteral meatus appeared entirely normal, but there was 500 cc. of residual urine. Thinking this residual might be due entirely to the urinary infection, the patient was given chemotherapy, but he did not improve until a bladder neck resection was done on July 14, 1948. At that time the child was at puberty, which we thought might be a factor. Since then he has developed well but continues to have recurrent urinary tract infection.

A second patient had the same complication, that is, bilateral ureteroceles with bladder neck obstruction at puberty. The pyelograms taken before the ureteroceles were opened demonstrated that this boy's upper urinary tract was badly damaged. After they were opened the boy had no urinary troubles until recently, when recurrent infection developed. The bladder neck was resected, but too recently for the result to be included in the paper or to determine whether permanent relief has been obtained.

UNUSUAL SYMPTOMS

We have mentioned some of the unusual symptoms but wish to present those of one 5 year old girl in detail.

This patient's complaints were not of urinary disturbance but of convulsive seizures, for which she had been studied thoroughly at the age of 3 years. She was returned when she was 5 with the same complaints, but this time her pediatrician happened to watch her try to void for a specimen and suddenly realized that the "seizures" were in reality only the child's efforts to void.

A cystogram made after voiding showed residual urine and demonstrated that there was no reflux even after five years of intense straining. The upper urinary tract was normal, and the child made an uneventful and permanent recovery.

The same day this child underwent resection another patient was subjected to the operation. She was 2 months old and had suffered urinary difficulty and infection since birth. The cystogram showed marked trabeculation with reflux and destruction of the upper urinary tract. The baby also had a congenital deformity of the rectum, which appeared in the middle of the perineum through a very tight opening. The dilatation of the bowel was thought to be on an obstructive basis. At the same time the bladder neck was resected this other abnormality was corrected, and the rectum dropped back to its normal location. From that time the child had no further bowel disturbance. She also voided well; the urinary infection was controlled; the nonprotein nitrogen dropped from 66 to 39 mg. per 100 cc. of blood, and the child was dismissed. She was returned three months later because of failure to keep up her weight and was found to have a serious yeast infection of the urinary tract. This was controlled with great difficulty, and again the child was dismissed. She was returned again four months later with the history of urine leaking out the umbilicus and an inability to gain weight. Because we believed the bladder neck had been thoroughly resected, but also because we believed the breaking open of the urachus was positive proof that the bladder neck was not functioning properly, a suprapubic tube was inserted, but the baby died soon afterward. The postmortem picture revealed that grossly all the obstructing tissue had been removed from the urethra, but again the thick, trabeculated bladder and dilated upper tract showed that the bladder was not functioning properly. Lengthwise sections through the urethrovesical juncture failed to reveal the nature of this dysfunction. The large bowel was normal.

The contrast between these two patients, one straining for five years without damaging her kidneys, and the other wrecking her upper tract within the first few months of life, is illuminating.

SUMMARY

A group of children are presented who have been treated either by simple dilation of the urethra or by the actual resection of tissue from the bladder neck. The statistics show that patients with marked symptoms and signs are more liable to need resection, and that boys are affected oftener than girls, but striking exceptions are noted. Difficulties in diagnosis and examination are discussed.

CONCLUSIONS

Resection of the vesical neck in either boys or girls is a worth while urologic procedure and should be performed when indicated, even though the bladder neck appears normal. This can be considered a minor operation with no operative mortality and usually requires a short postoperative hospitalization, ordinarily less than 72 hours. The absence of residual urine is not necessarily a sign that the operative procedure has been a success and that the child will remain well and develop properly.

ABSTRACT OF DISCUSSION

Dr. Miley B. Wesson, San Francisco: It is appropriate that this excellent paper of Drs. Howard and Buchtel should be presented in the home town of Dr. William E. Stevens, who, for over 40 years, has pioneered the study of the female urethra. *It has been 28 years since the late Franklin P. Johnson* published his embryological research, "The Homologue of the Prostate in the Female" (*J. Urol.* 8:13, 1922), but it was not until 1936 that David Mackenzie and Hugh Cabot made studies independently of the histopathology of the female bladder neck and urethra. Now, 14 years later, thanks to the mechanical ingenuity of Fred Wallace, Dr. Howard and his associates have been able to complete the study. Mr. Wallace recently showed me a baby telescope, with a large field, that would fit into the irrigating sheath of a no. 4 or 5 French catheter. When this is on the market, there will be no further difficulty in cystoscopy in baby boys. From now on, we will hear only about what not to do. The resectoscopist must never forget that the element of safety in cutting a female bladder neck is very small. He must be thoroughly familiar with the anatomy and also with Dr. Henry Weyrauch's findings on the depth of tissue destruction from cuts made with a spark gap current. Dr. Bentley Squier throughout his life referred to such treatment as burning, cooking or frying of tissues. I would like to report briefly the story of a 4 year old martyr to the electric current. She had a vesicourethrovaginal fistula. There had been difficulty in voiding and often residual urine of 1,500 cc. A diagnosis was made of a median bar with a muscular flap that acted as a cork, and on two occasions thorough fulguration was done. Retention was replaced by incontinence, and the family was instructed that nothing further could be done until the child was 16. After three unsuccessful repairs, one by that master technician, Dr. Guy *Hunner, I was able to close the opening, and at 14 she celebrated* her escape from bondage with a bonfire of all of her rubber pants.

Dr. A. M. Meads, Oakland, Calif.: My experience in treating lesions of the vesical neck in children is fairly limited. In my hands recurrent infections in the bladder have improved after dilation with sounds, showing that a contracted bladder neck or some simple type of obstruction in children does respond often to simple treatment. Personally I have not resected transurethrally any tissue in infants, but I have destroyed by fulguration obstructing bars and valves through a small cystoscope. This is safer where the urethra is very small. I have excised larger obstructions through a suprapubic incision with no regret in the few cases that I have seen. I purchased a small resectoscope two years ago, but I must confess that I have not used it, as I am still waiting for what I consider a proper case for such a procedure. I have seen a few young men and women of college age in whom a transurethral resection was indicated, but in these cases various degrees of hydroureter and hydronephrosis had already developed. This paper of Drs. Howard and Buchtel gives me food for thought. If these young adults had been treated in infancy, the extensive damage seen later could have been prevented. Most obstructive lesions seen in children are due to developmental defects and cannot be prevented, but early diagnosis and early removal of the obstruction could prevent the later damage. The small urethra in the very young must be dilated before a resectoscope can be passed. This dilation in itself is therapeutic. The small amount of tissue removed resectoscopically, in some reported cases, seems out of proportion to the spectacular improvement, unless the dilation has something to do with it. It is my custom when a distinct tumor mass is present (in one case a fibroma) to excise the mass through a suprapubic approach. I thus avoid the possibility of incontinence or damage to the bladder base. I can see a place for transurethral resection in children, but, as I treat comparatively few children, I have still not had an occasion to do one. The experience of Drs. Howard and Buchtel as given here today in their excellent paper will influence many of us, I am sure, in deciding when the resectoscope should be used in children.

Dr. Henry A. Buchtel, Denver: I should have mentioned that the vast majority of operations are done with the Thompson baby resectoscope. I think that is much the safest instrument, especially in a girl, because with the instrument you can remove exactly the tissue you wish to remove without the danger of sloughing or further injury afterward.

ADULT FORM OF CHRONIC PORPHYRIA WITH CUTANEOUS MANIFESTATIONS

REPORT OF SEVENTEEN ADDITIONAL CASES

Louis A. Brunsting, M.D., Harold L. Mason, Ph.D.
and
Robert A. Aldrich, M.D., Rochester, Minn.

The symptoms and laboratory features of chronic or intermediate porphyria may be similar to those of either the acute or the congenital forms, although the course is milder, as a rule. A blistering reaction of the exposed skin of adults, especially on the dorsa of the hands, in response to light, heat, or minor trauma is usually the first manifestation of this disease. The complexion assumes a dusky, bluish-red hue; the conjunctivae are injected, and hypertrichosis may occur. Other symptoms of a vague nature relating to the gastrointestinal system may occur, or nervous and mental disorders may develop. A familial incidence has been noted.

The factors which may contribute to the development of the manifest phase of porphyria are not well understood. In so-called acute idiopathic porphyria the barbiturates have long been incriminated. In chronic porphyria a damaging influence on the liver, either by disease, such as cirrhosis, syphilis, diabetes, or chronic amebiasis, or by hepatotoxic drugs or poisons, such as arsenic and particularly alcohol, seems to offer the precipitating insult. A number of examples have been reported.[1]

In this connection, one must distinguish between cases in which porphyrinuria accompanies hepatic dysfunction and those of true porphyria with jaundice or other involvement of the liver. In the former, there is no familial disposition and no ether-insoluble porphyrin is excreted. Gray, Rimington, and Thomson[2] described the case of a man 20 yr. of age, the skin of whose face and hands first became blistered in response to exposure to sun and to trauma; later, attacks of severe abdominal pain appeared, the earliest and severest of these being associated with jaundice. Initially, during the periods of sensitivity to light and abdominal attacks, the urine contained large amounts of porphyrins, including an ether-insoluble porphyrin, distinct from the known types of uroporphyrin and not yet identified. Between episodes, the amount of porphyrins in the urine diminished and increased in the stools; later, even these amounts gradually lessened as the clinical phase of the disease subsided.

Recently the occurrence of acute porphyria in three cases of diabetes was reported by Sterling, Silver, and Ricketts.[3] The diabetes had been of from three to 20 years' standing. No skin lesions were present. The occurrence of fatty infiltration of the liver in diabetes may offer a remote clue to the reason for the association of the two diseases, given a person with a suitable genetic background.

The symptoms of porphyria are complex; with an increased threshold of suspicion in this direction more instances of the disease will be recognized. Chronic porphyria, at least the type with cutaneous manifestations in adults, is commoner than is generally supposed; in the comparatively short period of the past five or six years we have observed 21 patients in whom the characteristic features of the disorder were brought to our attention by signs first appearing on the skin. Data concerning four cases have been reported previously.[1a,b]

This report is based on study of the 17 additional cases, of which two were chosen to be presented in order to illustrate briefly important factors of the disease. A discussion of the porphyrins involved (Table 1), the cutaneous and other aspects of the syndrome and the precipitating influences in the 17 cases (Cases 1 to 17) in particular will be considered.

REPORT OF CASES

CASE 2.—A man aged 46 yr., a butcher and farmer from Minnesota, came to the Mayo Clinic in the summer of 1949 because of a blistering eruption of the hands of five weeks' duration. Any relation to sunlight had not been noticed. After minor injury to his hands in his work, abrasions would form and, later, blisters which, when ruptured, were slow to heal. He also complained of loss of "pep," dating from a respiratory infection one year before. Since then his eyes had been bloodshot. At one time, 10 yr. previously, he had weighed 215 lb. (97.5 kg.), but by curtailing his beer drinking he had reduced his weight in two years to 160 lb. (72.6 kg.). He still used beer and as much as 1 pt. (473 ml.) of whisky on his monthly "binge." He had never noticed red urine.

Examination revealed that the weight was 154 lb. (69.9 kg.) and the blood pressure 126 mm. of mercury systolic and 90 diastolic. The exposed skin of the face and upper part of the trunk was a dusky, erythematous hue. Around the eyes the skin was colored bluish pink. There were irregular pigmented and depigmented areas about the face and neck. The cheeks had a waxy cast. The conjunctivas were injected, and the eyes had a rheumy appearance. The skin of the backs of the hands was hyperpigmented, with small irregular spots of colorless skin which were pink and showed telangiectasia. Over the dorsa of the hands and along the sides of the fingers there were a few small vesicles and crusted erosions of previous lesions of the same sort. Biopsy of the skin of the right preauricular area revealed microscopic evidence of dermatitis of nonspecific character.

Read before the Section on Dermatology at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 28, 1950.

From the Section on Dermatology and Syphilology, Mayo Clinic (Dr. Brunsting); the Division of Biochemistry, Mayo Foundation (Dr. Mason), and the Section on Pediatrics, Mayo Clinic (Dr. Aldrich).

Laboratory tests revealed only slight evidence of hepatic dysfunction. The urine showed primary fluorescence under the Wood light. Quantitative estimations of porphyrins are listed in Table 1. Porphobilinogen was not demonstrated. Fluid from blisters on the skin of the hands, a total of about 2 cc., was examined for porphyrins, and the results were negative.

The violaceous color of the skin brought up the possibility of polycythemia, but the values for hemoglobin and erythrocytes were within normal limits. The cell volume (hematocrit) measured 50 to 52%. Spectroscopic examination of the blood showed no indication of sulfhemoglobin or methemoglobin. There was no indication on physical examination of systemic or pulmonary hypertension.

The patient was observed at intervals for nine months as he followed his instructions regarding diet and total abstinence.

The blistering appeared and disappeared without regard to exposure of the skin to the sun, and the skin of the hands continued to be vulnerable to slight trauma. There was difficulty with shaving because of the tough beard and the tender skin of the face. After a period of six months, no more blisters developed although the skin over the knuckles was frequently abraded in the patient's work as a butcher; the color of the skin of the upper part of the body and the face remained unchanged.

CASE 15.—*A widow aged 64 yr., from Michigan, came to the clinic in December, 1949, because of a blistering eruption of the hands and fingers of six months' duration, which had been called "pemphigus."* In June a few pea-sized vesicles had first appeared over the backs of the index fingers; these exuded a clear fluid when ruptured and would form small ulcers which became crusted and sometimes infected; they healed slowly within two or three weeks. Repeated crops of such lesions appeared off and on during the summer months, without noticeable relation to sunlight, at first on the fingers and hands and later on the forearms and the ankles. Toward the winter months the process tapered off. Over the preceding two or three years, the patient and her family had noted a darkening of her complexion, as though she were wind-burned, and a considerable growth of hair had appeared on the face. During this interval the urine frequently had been tinted pink. There was no history of abdominal cramps. There was no similar skin condition in other members of the family.

The patient recalled that between the ages of 20 to 40 yr. she had had a recurring eruption of a different sort in which papular lesions had appeared for a short time each spring on the exposed surfaces of the skin. She remembered having taken arsenic intermittently for 10 yr. as part of the treatment for this disorder; instead of taking the prescribed number of drops of the medicine each day, she had taken a teaspoonful (4 to 5 ml.) without ill effect at the time. When she was 50 yr. old the papular eruption had recurred briefly.

For one year, at the age of 54 yr., she had been confined under psychiatric observation because of a reactive depression which had come on after her husband's suicide. After a series of shock treatments, she seemingly recovered and resumed her premarital occupation of teaching school, which she had continued without interruption until the time of her examination. The use of alcoholic drinks was denied.

Physical examination in December 1949 revealed abnormal conditions in the skin and the liver. The skin of the exposed surfaces of the face and neck was of a dusky, cyanotic hue and hyperpigmented. The conjunctivas were injected. There was hypertrichosis of the face. On the dorsa of the hands and fingers diffuse melanosis and a few crusted lesions, scars, and milia were evident. The liver was palpable 6 cm. below the costal margin. The weight was 135 lb. (61.2 kg.); the blood pressure was 130 mm. systolic and 76 diastolic. Dental examination revealed a severe degree of pyorrhea. The sulfobromophthalein test for liver function showed a 26% retention of the dye (Grade 3); there was no direct-reacting and 1.2 mg. of indirect-reacting bilirubin per 100 cc. of serum. Routine urinalysis showed normal urine. By Wood light the urine showed a strong primary fluorescence. The urine revealed large amounts of uroporphyrin and coproporphyrin, but tests for porphobilinogen were negative (Table 1).

Three months later, the patient returned. In the meantime she had followed a dietary regimen for cirrhosis. The infected teeth had been removed. Headaches and a state of mind similar to that of her depression of 10 yr. before had developed gradually. Her condition was characterized by lack of interest, hopelessness, suicidal trends, and insomnia. She had taken various forms of sedatives without relief. There had been no blisters, but the skin of the hands was easily traumatized.

Examination showed the same bluish-pink complexion as before. There were no recent excoriations on the backs of the hands and only a few scars and milia. The sulfobromophthalein test for liver function showed a 12% retention of the dye (Grade 2). The urine, which was tinted pink, contained large amounts of abnormal porphyrins. The porphyrins were present in the form of the zinc complex as determined spectroscopically with absorption maxima at 540 and 578 mμ. The Waldenström uroporphyrin was isolated, the melting point of the methyl ester being 258 to 260 C. No porphobilinogen was present. Psychiatric studies indicated a severe degree of reactive depression, and sanitarium management was advised.

Further examinations to indicate the nature of the hepatic dysfunction were not revealing. The urine showed no evidence of arsenic. Glucose-tolerance tests showed a diabetic type of response, but, in the absence of glycosuria and with a normal fasting level of blood sugar, this was interpreted as probably being related to the state of the liver.

Special studies were undertaken to determine the cause of the peculiar cyanotic hue of the exposed skin, without success. Both arterial and venous blood pressures were within normal limits. By manometric measurement, the oxygen saturation of the arterial and venous blood under various conditions of rest and exercise and with the inhalation of oxygen was found to be within normal limits. There was no evidence of polycythemia. Because of the hue of the skin and the presence of hypertrichosis, the possibility of Cushing's syndrome was considered briefly, but observations were not confirmatory. The blood pressure was normal. The roentgenograms of the skull revealed nothing abnormal. Concentrations of 17-ketosteroids and cortin-like substances in the urine were low on two separate occasions.

There was no record of a similar disorder in other members of the family; a sister, who accompanied the patient, appeared to be of normal health, and on two separate occasions her urine was examined and found to be free from abnormal porphyrins.

PORPHYRINS

Strictly speaking, the diagnosis of porphyria is established by the demonstration of uroporphyrin or the colorless chromogen porphobilinogen in the urine. Uroporphyrin is a porphyrin which appears abnormally, presumably as the result of the disturbed pyrrole metabolism of this disease. The urine contains a much higher concentration of uroporphyrin than do the feces and is more readily obtainable for laboratory analysis.

The presence of uroporphyrin in the urine is common to all types of porphyria. However, the form in which it is excreted may differ in the various clinical types. For example, the porphyrin in the urine of adults suffering from the acute intermittent form of porphyria is largely excreted as the zinc complex, but in children who have the so-called congenital form of porphyria the porphyrin appears in the urine in the free state. It is not possible at present to separate the clinical classes of porphyria on the basis of laboratory studies of the urine and feces alone. Nevertheless it is important that detailed information be recorded concerning the porphyrin metabolism in each case so that a better understanding of the abnormal metabolic processes may develop.

We would like to stress the wide variation in the appearance of the freshly voided urine. It is customary to speak of porphyric urine as being red or port wine in color; this observation was by no means the general rule in our cases. In some cases the specimen was almost normal in color, varying in shade from light yellow to dark amber. On the other hand, some samples were distinctly red. Thus, when porphyria is the suspected diagnosis it is probably unwise to discard a sample of urine because it is not red without first performing qualitative laboratory tests for uroporphyrin and porphobilinogen. Not all the discoloration seen in porphyric urine is due to the porphyrin itself. The urine contains other pigments which are not porphyrins but which probably are related as a result of the disturbance in pyrrole metabolism. Little is known about these pigments although, according to Garrod,[4] they were first emphasized by Hammarsten in 1891.

Qualitative Procedures for Identifying Uroporphyrin in Urine.—The quality of primary fluorescence in the near-ultraviolet region of the spectrum is an outstanding characteristic of the urine of children with so-called congenital porphyria. Although this phenomenon may occur in other forms of porphyria, it is often masked by the presence of other pigments or by the formation of a porphyrin complex with a metal such as zinc. A useful method for the qualitative identification of uroporphyrin in the urine has been described by Brunsting and Mason.[1b] An improvement [5] has been recently tried by one of us (Aldrich [6]) which makes use of the solubility of both uroporphyrin and coproporphyrin in an equal mixture of normal butyl alcohol and ethyl acetate. The bulk of the urinary impurities are separated from the porphyrin in the first step and left in the aqueous phase. This procedure is as follows:

> Shake a sample of fresh urine which has been acidified with a few cubic centimeters of glacial acetic acid in a separatory funnel with an equal volume of the 1:1 mixture of normal butyl alcohol and ethyl acetate. Discard the aqueous phase after it has completely separated. Wash the normal butyl alcohol-ethyl acetate mixture with three portions of distilled water. The organic-solvent layer will have a red fluorescence in the near-ultraviolet region of the spectrum. Then extract with small (3 to 5 cc.) portions of 10% sodium hydroxide; the porphyrins appear to go into the alkali almost quantitatively. Discard the normal butyl alcohol-ethyl acetate mixture and neutralize the sodium hydroxide with hydrochloric acid until the solution turns Congo red paper gray. Add 1 to 2 cc. of glacial acetic acid, and shake the solution with an equal volume of ether. Coproporphyrin goes into the ether, and if uroporphyrin is present it will remain behind in the aqueous phase. If large amounts of porphyrin seem to be present the ether extraction can be carried out several times to insure removal of all coproporphyrin from the water layer. Acidify the aqueous portion with hydrochloric acid, and examine it for red fluorescence in the light beam of the Pfalz and Bauer fluorophotometer equipped with a filter (Corning 5113) which gives the incident beam a strong intensity in the near-ultraviolet region of the spectrum.

Porphobilinogen.—Watson and Schwartz [7] described a qualitative method for the determination of porphobilinogen in urine. A rough estimate of the amount of porphobilinogen present can be made by use of a procedure described previously.[1b]

Spectroscopic Examination of Urine.—Examination of the fresh urine with the spectroscope will usually reveal whether the porphyrin is present in the free state or as the zinc complex. This complex may be formed with either the uroporphyrin or coproporphyrin. The zinc complex has strong absorption maxima at 537 and 578 mμ. If hydrochloric acid is then added to the sample, a change occurs in the absorption spectrum, and the maximal absorption then will appear at 550 and 594 mμ.

Quantitative Determination of Coproporphyrin and Uroporphyrin in Urine.—The method of Mason and Nesbitt [8] for determination of coproporphyrin was used in the study of our 17 patients. Quantification of uroporphyrin is difficult. Present methods give only a rough estimate at best. The problem is further complicated by the recent observation of British investigators,[9] who pointed out that the amount and character of the uroporphyrin in urine may be changed considerably by certain types of pretreatment of the specimen. The quantitative data reported herein were obtained by a method described in 1946.[1b]

Crystallization of the Porphyrin Methyl Esters From Urine.—Uroporphyrin octamethyl ester was prepared from the urine in only 1 case (Case 15) in the present series. The method used has been described elsewhere.[10]

[9] Gibson, Q. H., and Harrison, D. C.: A Note on the Urinary Uroporphyrin in Acute Porphyria, Biochem. J. 46: 154-157 (Feb.) 1950.

Observations in Seventeen Cases (Table 1).—Fourteen of the patients in our group were shown to have uroporphyrin in the urine on one or more occasions. In three cases in which two or more examinations were made for urinary porphyrins, uroporphyrin was absent on at least one occasion. This suggests that the excretion of uroporphyrin in this type of case may be intermittent. The urine of five of the 14 patients was examined for the porphyrin zinc complex, which was found to be present. Uroporphyrin octamethyl ester was crystallized from the urine in two cases and melted at 258 to 260 C. in one instance and at 273 C. in the other. This property is characteristic of the so-called Waldenström porphyrin. Evidence has been presented that this is a mixture of uroporphyrin I and an as-yet-unidentified urotype porphyrin.[11] The presence of the Waldenström porphyrin in urine has been considered a main feature of intermittent acute porphyria in which there is not dermal photosensitivity. Observation of this porphyrin in the urine of a patient who presented dermal photosensitivity emphasizes the present difficulty of classifying this form of porphyria on the basis of laboratory results alone. The quantity of uroporphyrin excreted per 24 hr. ranged from 22.4 to 0 mg.; most of the values fell in the range between 1 and 7 mg.

Each specimen was tested for porphobilinogen, and it was found in the urine of five patients. No uroporphyrin was demonstrated in the urine of two of these patients (Cases 10 and 14), while the urine specimens of the other three were positive for uroporphyrin. The colorless chromogen, porphobilinogen, was considered by Waldenström to be a characteristic observation in the urine of patients with acute intermittent porphyria and is not present in the urine of children with congenital porphyria who have skin photosensitivity.

Coproporphyrin was quantitatively elevated in 16 of the patients, but the relative proportions of the two coproporphyrin isomers I and III were not determined. Increased excretion of urinary coproporphyrin is the rule in porphyria; this is also a common observation in certain types of liver disease.[12] The amounts excreted in hepatic disease are usually much less than the values found in these patients. However, it is impossible to ascertain the relative proportion which the two pathologic conditions contributed to the high levels observed.

One of the patients in this series (Case 10) excreted neither uroporphyrin nor porphobilinogen on the two occasions when the urine was examined. The levels of coproporphyrin were well above normal. This person is included in the series because of the typical clinical picture of porphyria and because we believe that subsequent specimens of urine may be positive for either porphobilinogen or uroporphyrin, this case thus conforming to the intermittent behavior seen in others mentioned above.

Therefore we may conclude that in this series of patients the laboratory observations referable to porphyrin metabolism present some of the features of both congenital porphyria and acute intermittent porphyria. This conclusion agrees with the clinical picture, which is also one of a mixed type of porphyria.

CHANGES IN THE SKIN

Changes in the skin of patients with chronic porphyria involve the complexion and the dorsal surfaces of the hands. Diffuse melanosis of the exposed skin and hair, as well as discrete pigmented macules of the face, forearms, and hands, may occur. The hair of certain red-haired patients may turn black. In addition—and this point has not been emphasized previously—there is a characteristic change of hue in the complexion to a dusky, bluish red, and the conjunctivas become injected so that the patients, even the nonalcoholic ones, appear bleareyed and dissipated. This feature is a gradual process, often imperceptible to the person himself or to those near him, although it might be attributed to the effects of weathering.

The skin of the eyelids, the smooth periorbital zones, and various depigmented areas about the face and neck is tinted pink. Elsewhere on the exposed skin, with the pigmentation sometimes extending over the shoulders and upper part of the chest as well, the tissues are a suffused violaceous hue. The hair of the scalp and the eyebrows is usually darkened; the beard is tough, and women often have hypertrichosis. The facies bears a superficial resemblançe to that in Cushing's disease; the plethora reminds one of the skin in hypertensive states, polycythemia, or dermatomyositis. Detailed physical examination and study of the blood offer no adequate explanation for the changed complexion. Occasionally hypertension may occur. There is no disturbance of hematopoiesis; the hemoglobin, hematocrit readings, and the values for oxygen saturation of the blood are normal. There is no evidence of abnormal steroid metabolism. Spot checks reveal no sulfhemoglobin or methemoglobin. In the skin itself, no appreciable change in the capillaries or the larger vessels is apparent on microscopic examination.

An occasional small blister may appear on the face, the pinna of the ear, or the neck; the surface is easily traumatized. After exposure to heat or light, pruritus may occur, and in such cases the cheeks may show excoriations, crusts, razor cuts, and small scars. In a few instances in men, the sun-beaten skin of the nose, the cheeks, and the nuchal regions may become slightly granular and of a waxy cast, suggesting colloid milium, and, in fact, this impression is confirmed microscopically. In fixed sections, the tinctorial reaction of the underlying collagen resembles that seen in senile elastosis more than would normally be expected. Occasionally the exposed skin is toughened as in scleroderma.

Sensitivity to Light.—Although the blistering reaction of chronic porphyria appears on the sun-exposed surfaces of the skin, the exact photodynamic relation of the porphyrins to this condition has not been established. This statement is true likewise for congenital porphyria, in which photosensitivity in childhood is the predominating symptom. Attempts to reproduce the blistering reaction in the skin of patients with porphyria by exposure to natural sun or artificial light have not been successful. Perhaps it is necessary to have repeated exposure, as seems to have occurred in cases with the blistering reaction of chronic porphyria; in this connection it may be possible that certain porphyrins resident in the skin may be changed to a form in which they become active photosensitizers. In acute porphyria, cutaneous reactions seldom occur. Further study of the porphyrins in the skin may clarify this point.

HEPATOTOXINS AS PRECIPITATING FACTORS IN CHRONIC PORPHYRIA

In our 17 cases some damaging influence on the liver seemed to be the common factor in provoking the manifest phase of chronic porphyria (Table 2). Measurement of liver function was carried out, when possible, by the sulfobromophthalein, zinc sulfate, and thymol turbidity tests and by estimations of the serum bilirubin and the urobilinogen in the urine.

Among the toxic influences which can damage the liver and precipitate the obvious skin lesions of chronic porphyria, first and foremost is alcohol. The 12 patients with this syndrome discussed by Szodoray and Sümegi [1d] were alcoholic, without exception, and this relationship was confirmed by our own experience with the four patients who were the subjects of our earlier reports. The role of alcoholism is strikingly enhanced by the record of observations on the 17 patients whose cases are presented herein, of whom 12 admitted to the chronic use of alcohol in varying amounts for long periods (Table 2).

Two patients in our group had syphilis; one active, one ancient. Both used alcohol to excess. Syphilis was said to be present in six of the 12 cases of Szodoray and Sümegi.[1d]

Three patients in our series had diabetes; two of these three had neuropathy which had preceded the development of signs of porphyria by almost 10 yr. One of these was a moderate drinker. The third patient first discovered that he had diabetes two years after the onset of the blistering eruption of the hands. This patient was a teetotaler although the tests revealed a mild degree of hepatic dysfunction. An older brother, an alcoholic but not a diabetic, had had a blistering eruption of a similar nature in the summer sun for 15 yr. In one instance (Case 15), there was a diabetic glucose-tolerance curve as well as pronounced retention of sulfobromophthalein. In the absence of glycosuria and with a normal fasting level of blood sugar, the abnormal glucose tolerance was attributed to hepatic dysfunction. One parent of each of two nondiabetic patients was said to be diabetic.

Two women in this series (Cases 13 and 14) had a long irregular record of unexplained vague nervousness, seemingly on a functional basis; we could find no adequate explanation for the lighting up of the clinical signs of porphyria in middle life except incrimination of the drugs which had been used as sedatives or hypnotics.

Similarly, for the patient (Case 15) who exhibited an enlarged liver and gross impairment in tests of hepatic function and who first had classic cutaneous signs of porphyria after the age of 60 yr., the usual toxic factors were not apparent on the surface. We found that large amounts of arsenic, presumably in potassium arsenite solution, had been consumed in years past for the relief of cutaneous symptoms of another sort. However, the urine did not show the presence of arsenic at the time of our examination. The patient denied the use of alcohol.

A striking feature of the chronic form of porphyria as it affects adults is the relatively benign nature of the disease process, which is in contrast to the experience of persons with acute porphyria or children with manifestations of congenital porphyria. When it was possible, with the cooperation of the patient concerned, to eliminate the continual insult to the liver, as, for example, by the strict interdiction of alcohol and the institution of a dietary regimen directed in a general way, as is done in cases of cirrhosis of the liver, improvement resulted in health and well-being and in a lessening of the degree of photosensitivity. In the diabetics, the same favorable influence was noted when the patient was under adequate insulin therapy and dietary control. In the case of the patient with suspected but unproved arsenism (Case 15), there was a progression of the symptoms of porphyria and a relapse of a state of reactive depression which required institutional management. Data at hand are insufficient to permit valid conclusions as to whether the degree of porphyrinuria parallels the grade of clinical improvement of these patients.

† *A* to *AAAA* indicates alcoholism; *S*, neurosyphilis, arrested; *J*, jaundice (ancient); *SN*, neurosyphilis, active, treated with inoculation malaria; *DM*, diabetes mellitus with neuropathy; *D*, diabetes mellitus; *B*, sedatives, barbiturates; *As*, arsenic, and *JH*, infectious hepatitis.

The significance of porphyrins in human physiology and their relation to hepatic dysfunction and to photosensitization are not well understood. Patients with the clinical syndrome of chronic porphyria described herein appear to offer a convenient proving ground for this complex subject.

SUMMARY

A form of chronic porphyria is discussed in which the disease becomes manifest for the first time in adult life by cutaneous signs expressed as a blistering and erosive tendency of the skin, especially of the dorsa of the hands, on exposure to sun and trauma, as well as by a change in the complexion of the face and adjacent areas to a ruddy, violaceous hue. Associated symptoms of abdominal colic or nervous disorder occasionally occur. There may be spotted or diffuse melanosis of the exposed skin and the hair, and, occasionally, hypertrichosis. Milia are seen in the healed scars of the denuded and infected lesions of the hands.

Survey of the records of the 17 patients reported herein, including 13 men and four women, indicates that some damaging influence on the liver was chiefly responsible for the development of clinical symptoms. Alcoholism, the main offender, was present in 12 instances. Active diabetes mellitus occurred in three cases and syphilis in two; in one case there was a history of arsenism, and in two cases, of the use of barbiturates. In several cases more than one etiologic factor was suspected.

Under appropriate management the course was relatively benign.

Results of quantitative analysis of urinary prophyrins in the 17 cases are presented. The urine may be dark amber, sometimes pink and rarely red. In certain stages of the disease the urine may contain few or no abnormal porphyrins. Sometimes porphobilinogen is present.

Our experience indicates that the disease is commoner than is generally supposed.

In the light of our present knowledge, the exact classification of this type of porphyria is unsettled.

Mayo Clinic.

ABSTRACT OF DISCUSSION

Dr. Donald M. Pillsbury, Philadelphia: If I may digress for a minute, I think medical papers may be classified into the following groups: provocative papers—that is, those with which one may disagree; the type in which some fundamental new fact is elaborated, which sort occurs about once every five years, and then the kind in which there is an authoritative correlation of established basic facts and a discussion of their application to man. I think this paper is a beautiful example of the last-mentioned type. It is apparent in the literature that there is much interest in the problem of sensitivity to light. We are realizing that photosensitivity is a rather common state. Shelmire and Lamb showed clearly the varying objective changes in the skin which may be associated with sensitivity to light. Photosensitivity is commonly confused with other things, particularly contact dermatitis, and many times cases have been wrongly diagnosed as lupus erythematosus. Certainly the fixed erythema group of conditions may largely be due to photosensitivity. A point which Dr. Brunsting clearly makes is that persons with photosensitivity are by no means always subject to disturbances of porphyrin metabolism and, conversely, persons with such disturbances may not be photosensitive. This is a very curious fact which I hope some day we shall understand better. Another feature of the paper is the assertion that in persons with the syndrome he described there may be factors other than light which produce the eruption—heat, and particularly trauma. Dr. Brunsting is entirely correct that these persons are very sensitive; they have pronounced reactions to very mild trauma. The clinical recognition of these cases is generally fairly easy, although sometimes there are difficulties. The chemical methods involved are very difficult, and it is only in centers such as the Mayo Clinic that these complex chemical studies can be done completely. A very practical point which Dr. Brunsting brought out is that in the cases he discusses the clinical management has been reasonably satisfactory. With attention to the excessive intake of alcohol and an attempt to do something about associated hepatic disease, the clinical course is reasonably satisfactory.

Dr. Louis A. Brunsting, Rochester, Minn.: So far there has been no satisfactory explanation for the changes in color in the skin, particularly the violaceous suffusion of the exposed surfaces. There was no evidence of pellagra in any of the patients.

ENDOCRINE PATTERNS IN TERM PREGNANCIES FOLLOWING ABORTION

G. E. S. Jones, M.D.

and

Eleanor Delfs, M.D., Baltimore

The present study was undertaken to clarify, if possible, the underlying pathological factors occurring in abortion, with the hope of improving the rationale for therapy. The multiplicity of mechanical and physiological factors involved in the accomplishment of a normal term pregnancy suggests that the etiology of abortion must be manifold.

Reducing the problem to its simplest terms, there are two chief factors to be considered: the germ cells and the environment. To obtain a normal conception, both the sperm and the ovum must be normal, and fertilization must occur when both are recently shed; in short, not only must the gametes be inherently normal, but also the timing of fertilization must be optimal. Next, the environmental factors must be normal for proper growth and development of the normal trophoblast. If the environment is adequate, optimal trophoblastic growth should occur. Any degree of environmental inadequacy might presumably be reflected in the degree of defectiveness of the product of conception.

With the above concept in mind, the methods detailed below have been used to study a group of women with reproductive disorders.

The results of the studies on pregnancy of normal women [1] (Figs. 1 and 2), as well as of those on pregnancy terminating in abortion,[2] have been previously reported.[1]

From the Departments of Gynecology and Obstetrics, Johns Hopkins University and Johns Hopkins Hospital.

This study was made under a grant from The National Research Council, Committee on Human Reproduction.

This article has been shortened for publication in The Journal by the omission of Figures 5 to 10 and 13 to 16. These will appear in the author's reprints.

Read before the Section on Obstetrics and Gynecology at the Ninety-Ninth Annual Session of the American Medical Association, San Francisco, June 29, 1950.

[1] Jones, G. E. S.; Delfs, E., and Stran, H. M.: Chorionic Gonadotropin and Pregnanediol Values in Normal Pregnancy, Bull. Johns Hopkins Hosp. 75:359, 1944.

METHODS

Quantitative serum chorionic-gonadotropin assays have been used as a measure of trophoblastic growth and development. As this hormone is produced directly by the trophoblastic cells,[3] it is believed that the levels of this hormone reflect the normality of the growing conceptus. The known function of this hormone is to prolong the secretory capacity of the corpus luteum. The assay method employed is that developed by Delfs.[4] The normal levels were established by a consecutive study of 24 normal women throughout term pregnancies.[1]

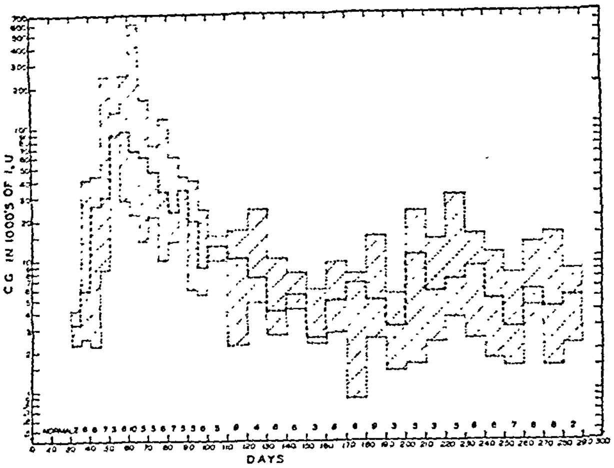

Fig. 1.—Serum chorionic-gonadotropin values throughout 24 pregnancies of normal women. The chorionic-gonadotropin values are recorded in international units per liter of serum on a semilogarithmic scale. The days of pregnancy are recorded from the first day of the last menstrual period. In this and the following figures, the extreme range of values is designated by the interrupted cross-hatched area, and the median value for each block is marked by the heavy interrupted line. The number of pregnancies studied, not individual assays, during every five-day period to day 100 and every 10-day period thereafter is recorded below the corresponding block.

Semen examinations have been done to check the male germ plasm.

Urinary pregnanediol determinations have been used as a measure of an important environmental factor. Pregnanediol is a metabolite of progesterone, the excretion of which is, in general, a mirror of progesterone production. Adequate amounts of pregnanediol can be interpreted as indicative of adequate progesterone production and indirectly as showing endometrial preparation for the nourishment of the growing trophoblast. Pregnanediol has been assayed by the Astwood-Jones[5] method for free pregnanediol. The criterion of normal has been the values found in the consecutive study throughout 24 normal pregnancies.[1] In the interpretation of the pregnanediol data it should be remembered that the major site of progesterone production during the first 100 or so days of pregnancy is probably the corpus luteum. After this time, the function is apparently taken over by the placenta. This is reflected in the relatively steady pregnanediol output during the first three months of pregnancy, followed by a gradual steady rise. These two phases of progesterone production will be referred to as the luteal phase and the placental phase.

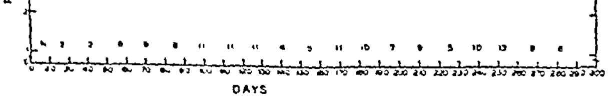

Fig. 2.—Urinary pregnanediol excretion throughout 24 pregnancies of normal women. The pregnanediol values are recorded in milligrams per 24 hr. on a semilogarithmic scale. The days of pregnancy are counted from the first day of the last menstrual period, and the extreme range of values is designated by the interrupted cross-hatched area. The median value for each block is marked by the heavy interrupted line. The number of pregnancies studied, not individual assays, during two-week intervals is recorded below the corresponding block.

Anatomical, nutritional, and metabolic functions were investigated as possible factors that might influence the development of the germ plasm directly or indirectly through the environment.

Curettages and hysterograms were done to evaluate the anatomical uterine environment. Determinations of serum vitamin E,[6] basal metabolic rate, blood cholesterol, and blood sugar, and when possible dextrose-tolerance tests, were carried out. Brucella agglutinations were done in many instances but did not prove helpful. Rh-typing was done but appears not to be significant. Basal temperature charts were kept when possible for evaluation of luteal phase and as a check on intercourse habits; these also helped in the early detection of pregnancy but have not been used for timing intercourse. Whenever possible, all studies were done when the patients were not pregnant. Cases associated with positive Wassermann reactions and untreated syphilis were excluded.

All defects found were treated when possible; if no defects were found, no therapy was given. When abortions occurred, the abortus were examined pathologically and grouped according to the Carnegie classification.[7] Abnormal trophoblastic development is designated by Carnegie Abortion Types I to V, Type I being the most abnormal and Type V the least abnormal. Type VI is a normally formed fetus that is not sufficiently developed for the duration of the pregnancy, and Type VII is a normal fetus of the proper developmental age.

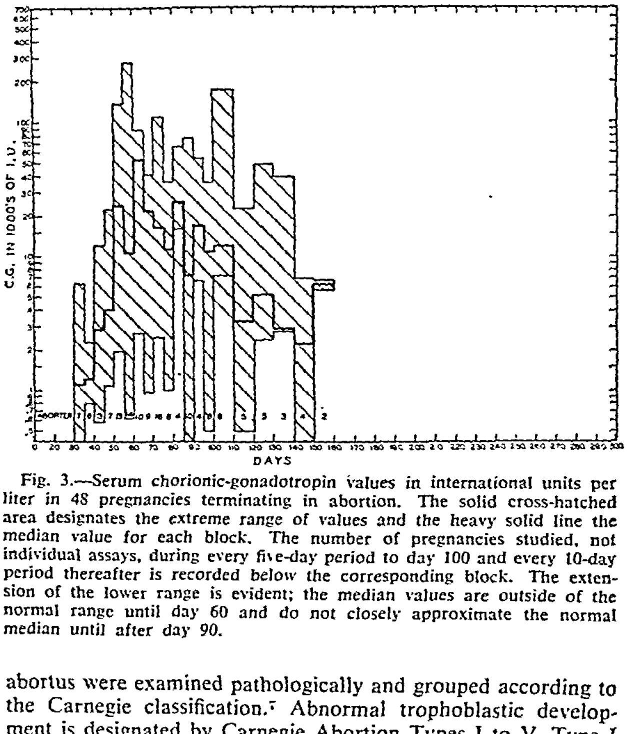

Fig. 3.—Serum chorionic-gonadotropin values in international units per liter in 48 pregnancies terminating in abortion. The solid cross-hatched area designates the extreme range of values and the heavy solid line the median value for each block. The number of pregnancies studied, not individual assays, during every five-day period to day 100 and every 10-day period thereafter is recorded below the corresponding block. The extension of the lower range is evident; the median values are outside of the normal range until day 60 and do not closely approximate the normal median until after day 90.

MATERIAL

One hundred seven women have been studied as described throughout 120 pregnancies. The actual reproductive histories are shown in Table 1, according to the outcome of the pregnancy studied, previous number of consecutive abortions, and previous term pregnancies. Forty-eight of the entire series of pregnancies studied terminated in abortion, and 72 ended successfully at term. Seventy-four of the pregnancies studied occurred in women who had had three or more consecutive abortions. This group of patients has been analyzed separately in a brief section on therapy.

CHORIONIC-GONADOTROPIN AND PREGNANEDIOL STUDIES

Abortion.—The median values of serum chorionic gonadotropin during the 46 pregnancies terminating in abortion were considerably lower than normal (Fig. 3). The most pronounced difference was observed before the 60th day of pregnancy. Day 1 is counted as the first day of the last menstrual period. The general shape of the curve is the same, but the rise is slow, the peak is less pronounced, and the fall is more precipitate and earlier. The fact that 19 of the abortions were associated with normal chorionic gonadotropin is reflected by the fact that the upper limits of the range fall within the range of normal. The pregnanediol levels are also lower than normal (Fig. 4). The median values are outside the normal or at the extreme lower limits, and the lowest value in the range is 0 until the 108th day. With the exception of one two-week interval, during which only two pregnancies were studied, there is no evidence of a placental phase.

TABLE 1.—*Number of Pregnancies Studied in Relation to Number of Previous Consecutive Abortions in 107 Patients (120 Pregnancies)*

Outcome of Pregnancy Studied	Previous Consecutive Abortions 0	1	2	3	4	5	Total Series	Total Patients with 3 or More
Abortion	3 (2)*	3 (1)	13 (7)	12 (1)	8 (0)	9 (1)	48 (12)	29 (2)
Term delivery	0 (0)	8 (2)	19 (2)	29 (12)	10 (2)	6 (0)	72 (18)	45 (14)
Totals	3 (2)	11 (3)	32 (9)	41 (13)	18 (2)	15 (1)	120 (30)	74 (16)

* Numbers in parentheses indicate patients in each group with previous term pregnancies.

The median curves are of statistical interest, as they demonstrate graphically the possibilities and limitations in utilizing the assays for prognostic purposes. Each patient's prognosis can be made accurately only on the basis of her individual values. The curves of individual patients lend themselves far better to interpretation and evaluation. The evidence has been previously presented in detail,[2] and the individual curves have been divided into four general groups: (1) those showing primary defects in chorionic gonadotropin, with normal or progressively falling pregnanediol values; (2) those showing defects in both chorionic-gonadotropin and pregnanediol levels; (3) those showing initially normal chorionic-gonadotropin values and primary defects in pregnanediol excretion, and (4) those with no defects.

There were eight pregnancies in group 1, i. e., cases showing chorionic-gonadotropin defects and only terminal pregnanediol defects. These might be interpreted as indicative of a primarily defective trophoblast (Fig. 5).

There were 17 patients in group 2, i. e., those with both abnormal chorionic gonadotropin and pregnanediol. In this group it is often impossible to be sure which defect played the major role in the abortion. Both could be primary defects and not interdependent. Occasionally, however, clues are obtained by evaluation of factors, such as known sperm defects, pathological type of previous abortions, or disturbed metabolic status. Figure 6 shows levels in a case of abortion due to possibly defective germ plasm with inadequate chorionic gonadotropin, resulting in inadequate luteal function. The semen specimen of the husband of this patient was defective on analysis. Figure 7 demonstrates the levels in a case that was of probably environmental origin, as the abortus was normal but smaller than expected for the duration of pregnancy. This was known to be correct as checked by the basal temperature chart and the initial appearance of chorionic gonadotropin in the serum. The last chorionic-gonadotropin value was in the normal range.

There were 10 pregnancies in group 3, i. e., cases associated with normal chorionic-gonadotropin levels and lowered pregnanediol levels. Three were due to early corpus-luteum failures; seven were caused by late placental-type failures. Figure 8 shows the values for a patient with corpus luteum-pregnanediol failure, and Figure 9, those for a patient with late placental-pregnanediol failure.

Group 4 consisted of nine pregnancies. This group showed no appreciable deviation from the normal in either the pregnanediol or the chorionic-gonadotropin curves (Fig. 10). Two patients showed terminally low values only after it had been estimated clinically that death in utero had occurred; both passed grossly normal fetuses.

Term Pregnancy.—The median values for serum chorionic gonadotropin and urinary pregnanediol obtained during 73 term pregnancies of women with previous reproductive difficulties have been compared with the normal ranges (Fig. 11). The curve nearly approximates the normal, and the median values are within normal limits after day 35. The early median values, however, still lag behind the normal median values, and it is not until about the 68th day that the chorionic-gonadotropin values finally approximate the normal. The median pregnanediol values approximate the normal very closely, but the extreme spread is greater, owing entirely to an extension of the lower values. It is noteworthy that, although in three two-week intervals values below 2 mg. were obtained, there were no values of 0 during the pregnancies that went to term. After 150 days values below 10 mg. occurred in only one interval. All these patients showed a consistent pregnanediol output, and, although values were distinctly below normal in some patients, an absolute deficiency did not occur (Fig. 12). There is a suggestion that the chorionic-gonadotropin level tends to drop more precipitously and sooner and that the pregnanediol rise occurs slightly later than among the normal women.

Thus, the placental take-over period in the group of women with poor reproductive histories may be more critical than in the normal women. A study of individual patient's values indicates this point more clearly than do median statistical values.

When individual cases are considered instead of median values, interesting observations may be made.

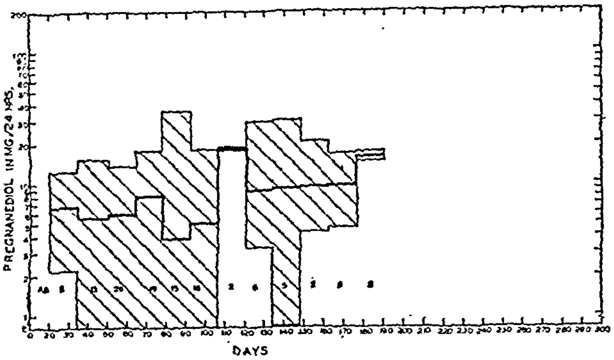

Fig. 4.—Urinary pregnanediol excretion in milligrams per 24 hr. in 48 pregnancies terminating in abortion. The solid cross-hatched area designates the extreme range of values and the heavy solid line is the median value for each block. The number of pregnancies studied, not individual assays, during two-week intervals is recorded below the corresponding block. The number of intervals during which a value of less than 1 mg. was obtained is notable. The median values are most abnormal during the placental phase.

The two patients in the group who showed distinctly abnormal chorionic-gonadotropin curves (Fig. 13) delivered very small babies (weighing 1,865 gm. and 2,580 gm.) at term; both were otherwise normal and have since done well. Four patients showed late chorionic-gonadotropin peaks. Another patient showed an unusually rapid chorionic-gonadotropin fall to an extremely low level, and this patient delivered on day 235 a 1,740-gm. baby that survived (Fig. 14).

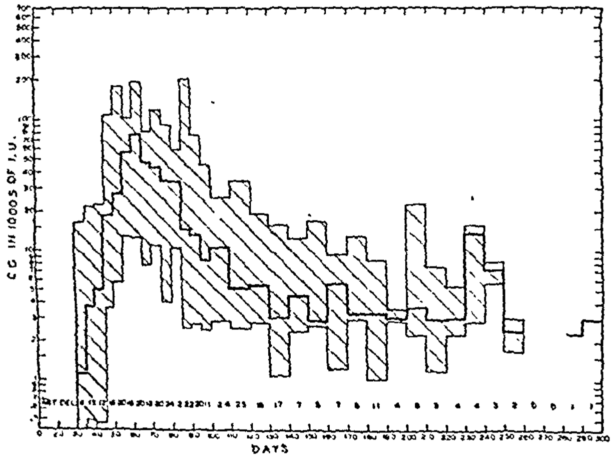

Fig. 11.—Serum chorionic-gonadotropin range and median values throughout 72 pregnancies in women with previous abortions. The general shapes of the median curve and range are similar to the normal. However, the median level is below normal until day 60, and the range throughout is broader.

Three patients showed consistently low pregnanediol values of both the luteal and the placental phase (Fig. 15). Six had luteal-phase pregnanediol deficiencies, two of which were associated with slow placental take-over periods (Fig. 16). An additional seven patients showed slow placental take-over periods, and three never established a normal placental pregnanediol level. One of these patients delivered prematurely, and the baby died at home of unknown cause after one month. Twelve had low placental-pregnanediol values.

THYROID STUDIES

The diagnosis of lowered thyroid function among the 107 women was on the basis of a basal metabolic rate of — 5% or less and/or a blood-cholesterol value of 250 mg. per hundred cubic centimeters or above in the nonpregnant state. Sixty-seven of the 120 pregnancies studied, or 55.8%, were associated with a lowered thyroid function. If only the series with true habitual abortion is considered, the percentage rises to 63.5%.

Twenty-six of the 67 pregnancies during which thyroid dysfunction occurred were associated with no other abnormality; four showed, in addition, low chorionic-gonadotropin levels; 21 were associated with pregnanediol deficiencies, and 16 had concurrent low vitamin E serum levels. Four women in the group had anatomical abnormalities; semen analysis for one woman's husband revealed abnormalities. These groups are not mutually exclusive.

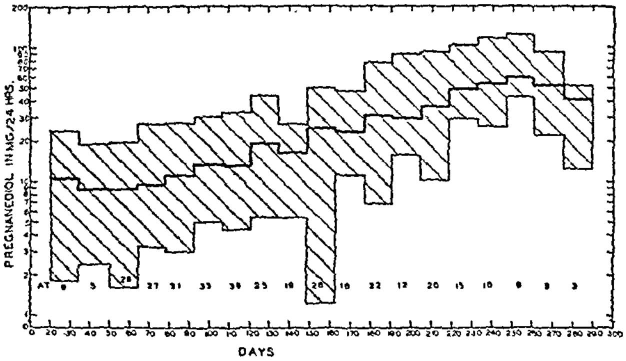

Fig. 12.—Urinary pregnanediol range and median values throughout 72 pregnancies in women with previous abortions. The lower range is much broader than the normal. Extremely low values are encountered occasionally as late as day 162. Median values are slightly lower than normal.

VITAMIN E

Seventy-eight women in the entire series were studied by means of serum-tocopherol levels. Twenty, or 25%, showed values below 0.9 mg. per hundred cubic centimeters, which has been judged as the lower limit of normal. Low vitamin-E levels occurred as a sole deficiency only twice. As a lowered serum tocopherol level was found oftener among the Negro patients and women with apparent nutritional disturbances, it is possible that this deficiency mirrors the general nutritional status of the patient.

SEMEN ANALYSIS

Semen specimens of 48 husbands were appraised, and seven were judged to be abnormal on the basis of the count, motility, and morphology. Six of the seven pregnancies associated with an abnormal semen analysis terminated in abortion. The woman who had a successful pregnancy was studied for the first time when she was eight weeks' pregnant. There had been abstinence from intercourse for one month before the specimen was obtained, and although the count was reduced the differential was normal. Such a finding may represent a technical error due to loss of the first portion in the collection.

Abnormal semen on analysis occurred as a sole deficiency only once in the total series. Although it would appear to be a defect with grave prognostic significance, it must be remembered that such defects can be corrected to some extent by urological care and improved general hygiene. Two of the women in the present series aborted at a time that the husband was found to have defective semen analysis. One of the women had lowered thyroid function and the other vitamin-E deficiency. Both women returned for study several years later, at which time normal semen specimens were obtained for analysis. Both delivered normal babies at term, the former with thyroid therapy and the latter without therapy, as during her second period of study the serum-tocopherol level was normal.

ANATOMICAL ABNORMALITIES

Anatomical abnormalities were encountered seven times in the entire series, but only once as a sole factor. Five of the seven pregnancies terminated in abortion. Three women who had bicornate uteri aborted. This condition occurred as a sole defect twice; once associated with a lowered thyroid function, and once with an abnormal semen analysis. Three women had myomas of the uterus; all were associated with lowered thyroid function, and two had had myomectomies. Two of these women aborted while receiving apparently adequate therapy; the third delivered at term. This woman had had the last of her three consecutive abortions after a myomectomy and prior to thyroid therapy. The seventh patient in the group had a malformation of the urogenital sinus with a rectovaginal cloaca; she also had abnormal thyroid function and carried to term successfully while receiving therapy.

TABLE 2.—*Correlation of Pathological and Endocrine Patterns in 41 Cases of Abortions*

	No. of Cases	Pathological Type of Abortus		Thyroid Status		Time of Abortion, Days			
		I-V	VI-VII	Low	Normal	0-90	91-120	121-220	221+
Group 1........	8	7	1	6	2	6	2	0	..
Group 2........	15	10	5	10	5	11	3	1	..
Group 3........	10	..	10	3	7	..	2	5	3
Group 4........	8	1	7	2	6	3	2	3	..
Totals........	41	18	23	21	20	19	9	9	3

DIABETES

There was only one woman in the series known to have had diabetes. The patient was a 34-yr.-old multigravida who had had two normal term pregnancies, followed by two abortions. In a second marriage she had a third abortion. During three subsequent pregnancies she was studied, and no abnormalities were found. No specific therapy was given in any of these pregnancies. The first went to term; the second resulted in abortion, and the third again went to term. The year after the last delivery, she displayed a diabetic-type dextrose tolerance curve. The relationship between the diabetes and the previous reproductive difficulties is problematical. Perhaps, however, women with late miscarriages and no abnormal findings deserve careful follow-up studies throughout the years.

PATHOLOGICAL CLASSIFICATION OF ABORTIONS

A correlation of the types of endocrine patterns with the pathological type of the abortus is show in Table 2. The more abnormal abortus are closely correlated with abnormal chorionic-gonadotropin values.

Among the eight cases in group 1, i. e., those showing defective chorionic-gonadotropin, only one abortus was normally developed; the other six were of a low Carnegie type.

There were 15 patients in group 2, i. e., those showing both defective serum chorionic-gonadotropin and pregnanediol excretion. Ten abortuses were defective, being Carnegie Types I to V; three were Carnegie Type VI abortus; two were Type VII.

Of 10 patients in group 3, i. e., those with normal chorionic-gonadotropin values and abnormal pregnanediol, eight delivered normally formed fetuses; one delivered an abortus that showed extrophy of the bladder and abdominal eventration, and one delivered a Carnegie Type VI, i. e., a normally formed, fetus but not of the proper developmental age. The latter two patients had early luteal failures.

Of the eight patients in group 4, i. e., those showing no hormonal pattern abnormalities, seven aborted normally formed fetuses and one had a defective abortus. It is of interest that the sperm of this patient's husband was defective on analysis.

When the thyroid status of these women was analyzed, a greater incidence of low thyroid function was correlated with defective chorionic-gonadotropin and low Carnegie types of abortus; the majority of abortions also occurred at an early stage of pregnancy. As might be expected, the women in group 3, i. e., those who had normal chorionic-gonadotropin values and low placental pregnanediol values, tended to abort late; three of these women carried to 220 days or more, two giving birth to living infants that survived several hours.

THERAPY

The aim of therapy has been to restore all demonstrable abnormalities to normal. Therefore, all defects found have been treated when feasible. An attempt has been made to study patients before they become pregnant, as it is our impression that the most effective treatment is usually given before or in the cycle during which pregnancy occurs. If no defect was found, no specific therapy was given.

Thirty-two to 96 mg. a day of desiccated thyroid has been the range of dosage, although an occasional patient has received 128 mg. a day. Experience with hyperthyroid states in women and excessive thyroxin administration in experimental animals [8] has amply demonstrated that overdosage with thyroid may be disastrous. Therapy is started three months before a pregnancy is advised.

Sixty milligrams of pregneninolone (progestoral®) [9] a day given orally, or 12.5 mg. of progesterone daily given intramuscularly, has been used for luteal-pregnanediol deficiencies. The most effective therapy is given in the cycle during which pregnancy occurs. With the use of basal temperature curves, it can be prescribed on the fifth postovulatory day and continued as long as indicated by urinary pregnanediol determinations.

---

[8] Gudernatsch, J. F.: Feeding Experiments on Rats: III. A Further Contribution to the Knowledge of Organ with an Internal Secretion, Am. J. Physiol. **36**: 370, 1915.

[9] The dose was determined by endometrial biopsy studies (Seegar, G. E.: Am. J. Obst. & Gynec. **39**: 469, 1940). Linguet® administration of pregneninolone does not enable one to reduce the dose, as it has been determined also by biopsy studies that 60 mg. of pregneninolone given sublingually produces minimal progestational changes in the properly prepared endometrium. There is no progestational change demonstrable in the majority of cases at a lower dose level.

The amount of progestogen necessary as supplementary therapy in the late placental-pregnanediol deficiencies is not well established. In the present series oral doses of 150 mg. a day of pregneninolone or intramuscular administration of 25 mg. of progesterone, has been generally employed. The pregneninolone has been preferred, as it is not recoverable in the urine as pregnanediol and, therefore, does not interfere with the interpretation of the pregnanediol data.

The dose of vitamin E as alpha-tocopherol (ephynal®) acetate has been 25 mg. a day for two or three months, or until the serum-tocopherol level is within normal limits.

Women with chorionic-gonadotropin deficiencies have not been treated, as these deficiencies have been interpreted as reflecting the poor developmental state of the conceptus. If this assumption is correct, the use of chorionic-gonadotropin as replacement therapy is untenable.

Dietary deficiencies have been corrected when indicated. Careful attention is also given to the general hygiene and habits of the patient.

It should not be necessary to say that good prepartum obstetrical care is the fundamental basis for all therapy. Without it, every specific therapy may prove futile.

EVALUATION OF THERAPY

The evaluation of therapy must be made on the basis of data from patients having three or more previous consecutive abortions. There were 74 pregnancies studied among patients in this classification. Sixteen of these women had had previous term pregnancies. Forty-five pregnancies carried to term, and 29 aborted.

In Table 3 the 74 pregnancies have been divided into three groups, according to the indications for therapy and therapy given. Group A represents those pregnancies during which indications for therapy were found, and adequate therapy was given. Group B represents those pregnancies during which therapeutic indications were found, but no therapy was given—usually because the patient presented herself for study when already pregnant or because the indications for therapy were not recognized in time. Group C represents those pregnancies in which no basis for therapy was discovered, and, therefore, no therapy was given; this group includes those women in whom an anatomical abnormality and the husband's defective semen on analysis were the sole defects.

When the pregnancies are thus classified according to abortions and term deliveries, it is apparent that there is an 85% therapeutic success in group A, or the treatment series. In group B, in which therapy was indicated but not given, the term delivery rate is only 21%. It is of interest that the five successful pregnancies in this group all showed placental types of pregnanediol deficiencies, and two terminated in premature deliveries with live babies that survived. As can be seen from a careful study of the pregnanediol range found among this group of patients (Fig. 12), the pregnanediol deficiencies were relative to those in pregnancies of normal women, not absolute. It is possible that women with such deficiencies are maintained in a relatively delicate state of balance and may carry at least to viability if nothing untoward occurs to disturb this balance. In Group C, in which no therapeutic indications were discovered, and, therefore, no specific therapy was given, 50% of the pregnancies ended in term deliveries. By adding groups A and C together, the total number of patients managed according to indications is obtained. Forty of 51 pregnancies, or 78%, carried to term. This figure probably best represents the expected therapeutic success for women with habitual abortion, using the method of case management described, with present methods of investigation and adequate therapy.

All the infants delivered in the present series were physically normal. There is no reason to believe, from the material at hand, that therapy in women with repeated abortion enhances the probability of a malformed child.

TABLE 3.—*Summary of Therapy and Therapeutic Indications Among 74 Pregnancies Studied in Women with Three or More Consecutive Abortions*

	Aborted	Term	Total	% Success
Group A				
Therapeutic indications:				
Therapy given	6	35	41	85
Group B				
Therapeutic indications:				
No therapy given	18	5*	23	22
Group C				
No therapeutic indications:				
No therapy	5†	5	10	50

* In all five cases patients had pregnanediol deficiencies (2 premature babies).

† In one case the husband's sperm was defective. In a second case there was defective sperm and bicornate uterus. A third patient had a bicornate uterus.

SUMMARY AND CONCLUSIONS

A method for the study of women with reproductive problems is presented in an effort to clarify some of the etiological factors involved in such disorders. With the diagnostic methods used, certain divergent groupings have emerged. It is to be hoped that, with the acquisition of further knowledge in the field of reproductive physiology, additional diagnostic aids will become available for the extension of this method of approach.

One hundred and twenty pregnancies have been studied in women with abnormal reproductive histories. Repeated serum chorionic-gonadotropin assays, determinations of urinary pregnanediol, basal metabolic rate, blood cholesterol, blood sugar, dextrose-tolerance curves, and serum tocopherol, and analysis of husband's semen, in addition to the routine gynecologic type of investigation, have been made. Forty-eight of 120 pregnancies resulted in abortion and 72 in delivery at or near term.

A comparison of certain endocrine patterns during term pregnancies in women having poor reproductive histories with those in normal women shows that both the median chorionic-gonadotropin and the pregnanediol levels are somewhat lower than normal. The median values during pregnancies terminating in abortion are still lower than those proceeding to term and markedly lower than those noted during pregnancies of normal women.

Four types of endocrine patterns are recognized among the pregnancies terminating in abortion, and it is apparent that such patterns may be useful in clarifying the etiology of abortion. The same patterns are discernible in a less exaggerated form among term pregnancies of women with poor reproductive histories.

The pathological types of abortus are closely correlated with the hormonal patterns.

In the majority of instances multiple deficiencies were found. Lowered thyroid function occurred 67 times, pregnanediol deficiencies 39 times, chorionic-gonadotropin deficiencies 27 times, vitamin-E deficiencies 20 times, and semen abnormalities and anatomical pelvic defects each seven times.

The aim of therapy has been to correct all demonstrable deficiencies. When this was accomplished, the therapeutic success was 78% in patients with three or more previous consecutive abortions. If those pregnancies in which no therapeutic indications were found are excluded, the therapeutic success rises to 85%.

715 N. Charles St. 1 (Dr. Jones).

ABSTRACT OF DISCUSSION

Dr. J. P. Pratt, Detroit: One of the fallacies regarding the importance of the corpus luteum in the maintenance of pregnancy and abortion began nearly half a century ago with the experimental work of Fraenkel on rabbits. When he removed or destroyed the corpus luteum during pregnancy in those animals, abortion always resulted. It was assumed that the cause of abortion in women had been found, and numerous preparations of corpus luteum, now known to lack potency, were employed. Excellent results were acclaimed. Gradually, it was learned that species differed a great deal in their needs for the corpus luteum to maintain pregnancy. It would be possible to classify different species according to this relationship, with rabbits at one extreme needing the corpus luteum throughout pregnancy and guinea pigs at the other extreme. Just where the human being belongs in this series is still debatable, but there is good evidence that, in general, the importance of the corpus luteum has been overrated. Numerous instances are on record showing that pregnancy has proceeded normally even though the corpus luteum had been removed as early as the 21st day of the cycle. It was stated that the known function of chorionic gonadotropin is to prolong the secretory capacity of the corpus luteum. May I ask Dr. Jones whether she refers to the human being or some other species. If the reference is to human beings, how can one explain the finding of a normal level of chorionic gonadotropin in 18 of 41 women who aborted? It would be still more enlightening if we knew how many women with a low level of chorionic gonadotropin carried their pregnancy normally to term. It is accepted that the trophoblast secretes chorionic gonadotropin. What explanation is there for such a rapid rise to a peak about the fiftieth day? If it is to be assumed that the level of chorionic gonadotropin reflects normality of growth of the conceptus, why does the level of secretion fall so early in normal pregnancy while the conceptus is still growing? Is it fair to assume that chorionic gonadotropin is a quantitative indicator of normalcy of the trophoblast? Pregnanediol determinations were offered as evidence of normalcy of pregnancy. It was assumed that the placenta secretes progesterone and that the placenta takes over the process of supplying progesterone after about the 100th day of pregnancy. It is established that progesterone is found in the placenta, but is there any satisfactory evidence that it is secreted by the placenta? Of the 41 women who aborted, 16 had normal pregnanediol levels. This corresponds with other reports that women with normal or even high levels have aborted and women with persistently low levels of pregnanediol have delivered normally at term. It is interesting to note that many variations from normal were found; sometimes several in the same patient. The report of the assays of chorionic gonadotropin and pregnanediol in this group of patients is a distinct contribution.

Dr. Pendleton Tompkins, San Francisco: Arthur Hertig and others found that more than 50% of aborted embryos were anatomically abnormal. If more than half of all abortions are due to fetal maldevelopment, it would seem to be impossible—or unwise—to salvage more than 50% of the jeopardized pregnancies. So strong has been the impression made by Hertig's figures that a question has arisen with regard to reports of 70 and 80% success in the treatment of repeated abortion. The issue is whether the successes may be attributed to the therapy administered, or whether the successes are due to the happy chance that a "better" ovum has been fertilized by a "better" sperm. Dr. Jones implies that a husband with a "deficient sperm count" may be responsible for fetal malformation. I have not seen any data on the human being that proves that sperm of poor quality produces embryos of poor quality. Some anomalies are due to malnutrition of the mother, some to viruses, and some to genetic factors. After adding all these known influences we are left with no explanation for the majority of abnormalities. That the conceptus might be influenced by its environment is a foregone conclusion; nevertheless, it is a conclusion not easily proved. The work by Dr. Jones is important because it demonstrates by objective measurements (hormone assays) a correlation between a faulty endocrine environment and a defective embryo. She concludes that the environment influences the development of the embryo. The reverse position, namely, that a faulty embryo usually produces an abnormal endocrine balance, is scarcely tenable for, if this were true, administration of hormones to the mother should not be effective in preventing abortion. We ask at what stage in gestation this environment is requisite. The author secured the best results when corrective therapy was first administered in the cycle of conception or in the previous cycle. Her results re-enforce the suggestion by Rutherford and others that in cases of habitual abortion progesterone should be administered immediately after ovulation when it seems likely that fertilization has occurred. The basal temperature chart is useful when such a plan is undertaken.

Dr. G. E. S. Jones, Baltimore: Dr. Pratt asks if we mean chorionic gonadotropin prolongs the life span of the corpus luteum in the human being. We did mean that. Experiments using chorionic preparations in normal, nonpregnant women substantiate this fact. Dr. Pratt asked: If this is true, how do we account for the findings of normal chorionic gonadotropin in 18 of 41 women who aborted? I think chorionic-gonadotropin failure, or trophoblastic abnormalities, are only one cause of abortion. Abortion in women with normal chorionic-gonadotropin values must have some other cause, such as anatomical or nutritional faults. How do we account for the fact that the trophoblastic secretion of chorionic gonadotropin rises to its peak at the 50th day and then declines? The histological evidence indicates that the trophoblastic cellular activity is also at a peak about that time. Perhaps the corpus-luteum cells are increasingly difficult to stimulate, and, therefore, more and more hormone may be necessary. After the 50th day it is possible to remove the corpus luteum in the human being and still maintain the pregnancy. This is another indication that the placenta takes over the progesterone function. In animals, of course, even animals as high in the scale as the ape, the chorionic gonadotropin is not produced after the first trimester of pregnancy. This may indicate that chorionic gonadotropin has no function after the first trimester of pregnancy and is simply an additional protective mechanism in the human woman. Why are there women with normal pregnanediol levels who aborted and ones with low levels who did not abort? A normal pregnanediol level is no more proof against an abortion than a normal chorionic-gonadotropin value. Mechanical and anatomical factors may play a part in such case, as well as other unknown factors. Most of the patients who showed low pregnanediol levels early in pregnancy and did not abort were being treated with pregneninolone, which, although a progestogen, is not excreted as pregnanediol. We believe this may have helped such women to continue to term. Some of the women with low levels later in pregnancy apparently could carry to term without treatment. This is another indication that the deficiency is a relative rather than an absolute one.

SKIN GRAFTING FOR THE GENERAL PRACTITIONER

Donald E. Barker, M.D., Los Angeles

Since the last war, there has been a marked shift of skin grafting from the specialist to the general practitioner and general surgeon. The practitioner in the small town is unable to send his smaller burn cases to the city and therefore has to treat them himself. Those who have had little experience in this field are confused by the vast array of literature and unexplained terms of grafting. An attempt is made here to provide a simple means of grafting for physicians practicing in small communities. As many articles have been written on the care of wounds and burns, repetition here would be of little value. To the general practitioner, much of the material written about grafting is either not on hand or unobtainable at the time. For this reason, only the simple dressings are described here.

Any wound can be grafted. However, one is more successful if the wound is clean. The term "clean" is confusing, but it means that the area to be grafted should be free of necrotic tissue and gross pus. If there is a pronounced purulent discharge from the wound, a simple dressing saturated with a 2% boric acid solution every three hours for two to three days will remove the gross contamination. No open wound is ever entirely free of some discharge. One may also take a knife and scrape off the old granulations several days before grafting and put on a dressing to which has been applied 2% boric acid ointment. This is wrapped securely so that a firm pressure is applied.

METHODS OF SKIN GRAFTING

There are a number of means of taking skin grafts. The use of a long skin grafting knife is not advisable because of the training necessary to master its use. I do not like the pinch grafts either, because they almost double the operating time and also cause bad disfigurement of the donor and recipient site. The machine I prefer is the vacutome, which uses only suction for obtaining the grafts. It is inexpensive and simple to operate; anyone can cut a graft with it. There are no special glues or tapes to buy nor does it get out of order. Figure 1 shows the machine ready for use. The thigh is the donor area used by most physicians in obtaining a graft. I usually prepare the thigh all the way around, and then place a sterile rolled-up sheet under the thigh to flatten it out so that a wide graft can be obtained. A graft taken at 0.015 of an inch thick is ideal for any situation, although some persons recommend one thickness of skin for one procedure and another for some other procedure. The depth of cut is simply adjusted by turning the thumb screw two notches to the left. A thin layer of petrolatum (vaseline) is applied to the skin where the graft is to be taken. The vacutome is attached to any standard suction found in any hospital. The machine is then pressed on the skin, and the knife is rotated into position so that it touches the skin. With easy strokes, the knife is moved back and forth while the machine is slowly pulled along the skin. Care is taken that the blade holder is held tight against the box at all times. The graft that has been cut rolls over the back of the blade holder. When the desired length of graft is obtained, one lifts the machine off and cuts the graft with a pair of scissors. Figure 2 shows a Steinmann's pin inserted under the skin for countertraction. The graft obtained is shown in figure 3. This machine has several advantages over the glue type. They are as follows: (1) Time is saved when glue is not used. (2) The glue does not have to be removed from the skin after the graft is taken. This often causes the skin to become rolled and glued together unless it is handled carefully. (3) Humidity and sterilizing solutions do not affect the area where the graft is obtained. Figure 4 shows a graft one year after operation.

Another method of obtaining grafts is the use of the dermatome or glue machine. The depth of cut can be adjusted here in a similar manner to that of the vacutome. The trick in the use of this machine is for one to cleanse the skin with tincture of benzalkonium (zephiran®) chloride or thimerosal (merthiolate®) and after it has dried, to thoroughly dry the area by wiping it repeatedly with an ether-soaked sponge. The glue is applied to both the drum of the machine and the skin and should be allowed to dry for five minutes before the machine is applied to the skin. This glue is on the order of the common tire cement and holds better after a long period of drying than when it is just applied. The drum is applied to the skin and held in place about 10 seconds to get union, and then one should very carefully bring the knife into position against the skin. If the glue does not hold, it is useless to try and press it on again, as it has pulled off from either the skin or the drum. In this case, it is necessary to take the drum off and reapply the glue. The graft is cut when the blade moves along in a manner

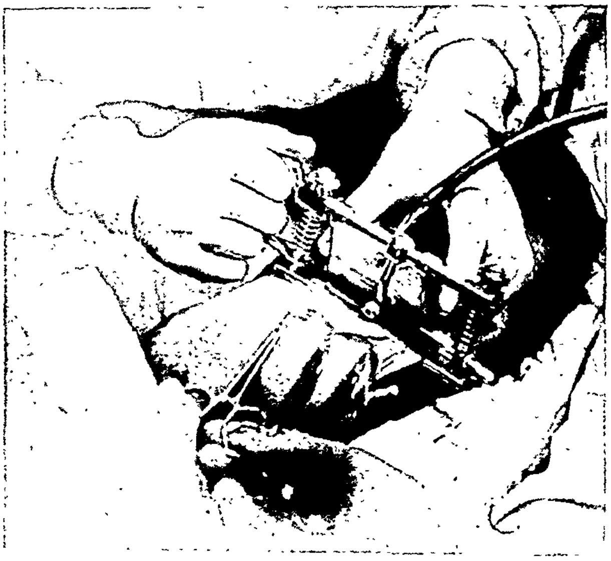

Fig. 1.—Photograph showing vacutome in position.

similar to that of the vacutome. After the graft has been cut, it is picked up on the corners with hemostats and pulled off the drum. Care should be used so that the skin surfaces do not touch, or they will stick together. To prevent sticking, the surface may be dusted with sulfathiazole powder or petrolatum may be applied.

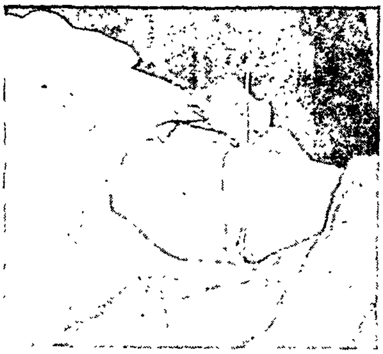

Fig. 2.—Photograph showing Steinmann's pin used for countertraction.

TREATMENT OF GRAFTS

There are many methods in treatment of the grafts. I will explain only the simple ones that can be used with the facilities at any hospital. On my grafts, I like to make drain holes with a no. 11 blade and then sew them in place. Bleeding should be controlled prior to application of the graft. I prefer to sew my grafts in place with a no. 3-0 silk; however, any kind will do. A method that forms a secure dressing is to leave the ends of some of the sutures very long so that they can be used to tie a number of fluffed-up sponges in place and give localized pressure. The simplest type of dressing to use over a graft is 4 by 4 in. gauze opened up and laid on the graft. On top of this should be placed a number of flat sponges moistened with either 2% boric acid or normal saline solutions. A few fluffed-up sponges on top of this forms an ideal dressing. I usually tie them in place with the sutures, although this is not necessary. It is bandaged with a sterile elastic bandage. Ordinary rolled bandage is poor because of its inability to give steady pressure. The dressing is moistened every three hours with either boric acid or saline solutions.

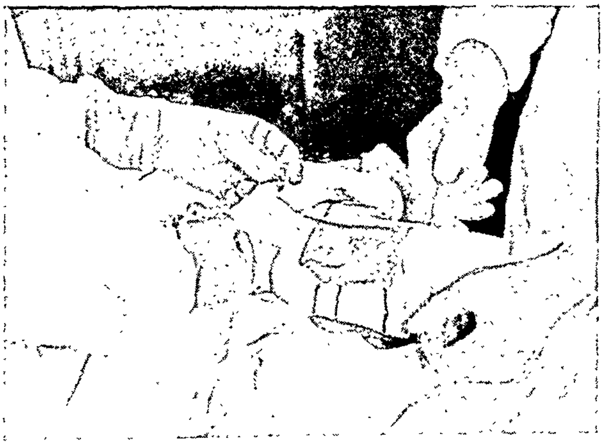

Fig. 3.—Photograph showing graft obtained over a firm base without suction.

An alternate method is for one to apply strips of petrolatum gauze over the graft and on the top of this, place the sponges and the fluffs. If petrolatum gauze is not available, one can cut a number of strips of 2 inch roller bandage and apply sterile petrolatum or nitrofurazone (furacin®) to these. I usually use antibiotics for the first week as an added precaution. Over the donor area, strips of vaseline gauze are applied, and a pressure bandage similar to that on the graft is used.

When should one look at the graft? If there is no odor from the dressings and the temperature remains under 100 F., I ordinarily do not change the dressings for four to five days. However, if the dressing becomes foul or the temperature spikes to 102 to 103 F., the dressing should be very carefully removed as early as the end of 48 hours. When the dressing is changed, any pustules or blisters in the graft are opened. In case of any infection, wet dressings are immediately applied. Once the initial dressing has been changed, I always change the dressing every other day. This gives better healing. The sutures are removed on the eighth day, and usually all the bandages may be removed by the eighteenth day. On the legs, it is usually wise to apply an ace bandage for a period of three months to prevent the swelling of the leg following this immobilization. It is a good idea to have the patient apply hydrous wool fat (lanolin) or petrolatum to the graft for several months to prevent drying of the graft.

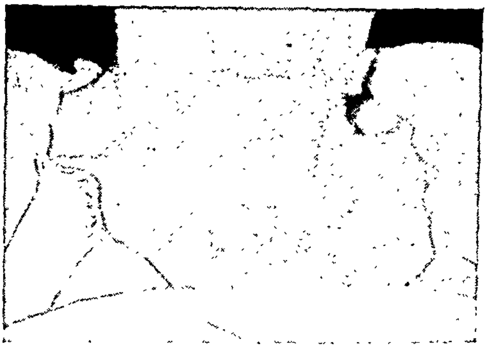

Fig. 4.—Photograph showing neck graft one year after operation.

SUMMARY

A simple method of taking and applying skin grafts is described. An attempt has been made to limit the materials used in the care and preparation to those found in any hospital or clinic.

The Physician's Responsibility.—We owe it to our patients to keep our skill at its peak by practicing, in our own expenditure of physical and mental energy, the moderation which we preach to them, and by utilizing the cultural and spiritual resources afforded by wholesome recreation, reading, home life, and worship. An extensive practice is exhausting; and when we become overtaxed our medical judgment wavers, our patients are denied their rightful consideration, and we become guilty of that assembly-line type of treatment which we so greatly deplore in England.—A. M. Phillips, M.D., The Physician's Responsibility, *Journal of the Medical Association of Georgia*, April, 1951.

CLINICAL NOTES

SARCOIDOSIS DIAGNOSED BY MEANS OF SUBCLAVIAN LYMPH NODE BIOPSY

REPORT OF A CASE

Lieutenant Commander Harry A. Weiss (MC), U.S.N.; Lieutenant Commander Robert M. Campbell (MC), U.S.N.; Lieutenant Commander George C. Budenz (MC), U.S.N., and Commander Carl M. McCandless Jr. (MC), U.S.N.

This case is reported because of its interesting features and because it illustrates the use of a new diagnostic aid in confirming a clinical impression of pulmonary sarcoidosis.

Frequently a histological diagnosis of Boeck's sarcoid is impossible because there is no superficial lymphadenopathy. In a series of such cases recently reported, a method of obtaining lymph nodes or lymphoid tissue from the fat-filled space overlying the scalenus anticus muscle was described by Daniels.[1]

REPORT OF CASE

The patient, a 48 year old man, was admitted April 5, 1949 "for a check-up."

In November 1941 he had had influenza, which persisted despite the usual palliative measures. He was studied at a hospital for six weeks. Because of the chronic cough with expectoration of mucoid sputum, weight loss, fatigue, increased erythrocyte sedimentation rate and appearance of the chest roentgenogram, a diagnosis of pulmonary tuberculosis was made. Results of the sputum studies and the tuberculin test were negative. He was discharged after being advised as to diet, rest, etc. After a month he felt well and returned to his clerical work. The patient remained well except for a mild cough with expectoration of 150 ml. of greenish sputum daily and periodic night sweats. He maintained his weight. Beginning in 1943 he infrequently had blood-streaked sputum. Various physicians followed him during this period. In 1945 ease of fatigability developed, and he lost 50 pounds (22.7 Kg.) of weight in the next three years. Since 1945 he had been under constant medical supervision by private physicians, a medical school clinic, a county sanatorium and a naval hospital. During the past eight years, results of stains, cultures and inoculations of guinea pigs with sputum and bronchial washings were repeatedly negative. The patient had semiannual chest roentgenograms. He estimated that the reactions to at least 30 tuberculin tests had been negative. Reactions to the tuberculin tests performed on his wife and 10 year old son were negative. At one time Pseudomonas aeruginosa was cultured from his sputum, and he was subsequently treated with a vaccine, penicillin, sulfonamides and streptomycin, without apparent effect. He had had asthma since 1943 and obtained relief from tripelennamine (pyribenzamine®) hydrochloride. Skin tests showed sensitivity to bananas. His weight had been constant during the past year. He requested admission for a periodic check-up.

The review of systems disclosed no other abnormalities.

His past history included mumps, whooping cough and measles in childhood and a Gonococcus infection in 1925. His family history was not pertinent except for its negativity. There were no known cases of tuberculosis.

Examination showed a middle-aged man in no distress except mild shortness of breath. The temperature was 98.2 F., pulse rate 86, and respiratory rate 26; the blood pressure was 98 systolic and 64 diastolic. The trachea was deviated to the left. There was a respiratory lag throughout the left hemithorax. Breath sounds were diminished at the base of the right lung. There was dulness over Kernig's isthmus bilaterally. There were crepitant rales over the apexes of both lungs. There was moderate clubbing of the fingers. The vital capacity was 2,800 ml., 65 per cent of the calculated normal. There were no palpable lymph nodes.

Results of the Kahn blood test were negative, and the blood cell count and urinalysis were normal. The sedimentation rate of erythrocytes was 25 mm. in one hour. Serum protein was 5.7 Gm. per 100 ml., with 3.0 Gm. of albumin and 2.7 Gm. of globulin. Reaction to the histoplasmin skin test was positive; reactions to the coccidioidin and tuberculin skin tests were negative. Results of the smears and cultures of the sputum and bronchial washings were negative. The Kveim test was not performed. The electrocardiogram showed left axis deviation.

We were able to obtain chest roentgenograms dating to January 1945 from outside authorities and to compare them with current roentgenograms. The earliest showed a diffuse fibrotic infiltration occupying the upper half of the right lung field and a similar but less extensive infiltration of the left midlung field. The pleura was thickened over the apex of the right lung, and small calcifications were present within the bilateral lesions. The nodes at the root of the right lung were enlarged and were of the type sometimes described as "potato nodes." The right hilus was drawn laterally by the fibrosis. Emphysematous changes were present in both bases, and adhesions to the diaphragm and pericardium were present. Roentgenograms of July 1947 and August 1948 demonstrated bilateral progression of the lesions with infiltration into both bases. The lesions appeared softer than previously, although more calcifications had developed. The right hilus remained enlarged, and the left hilus had increased in size.

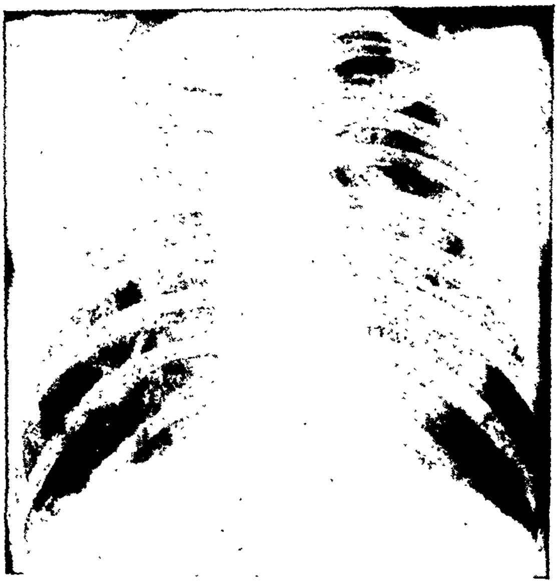

Fig. 1.—A representative chest roentgenogram view.

The examination of April 1949 showed bilateral decrease of the lesions, which were now entirely fibrotic. The right hilus

McCandless).

[1] Daniels, A. C.: A Method of Biopsy Useful in Diagnosing Certain Intrathoracic Diseases, Dis. Chest **16**: 360 (Sept.) 1949.

had decreased in size, although the left hilus had remained enlarged. At no time in this series of roentgenograms was cavitation demonstrated. In view of the long series showing extensive bilateral changes of fibrosis and calcifications, but without cavitation, the presence of a chronic fungus infection should be considered, although tuberculosis must be ruled out. The calcifications were of the type described in histoplasmosis. The enlarged hilar nodes suggested sarcoidosis. Figure 1 shows a representative chest roentgenogram view.

Because of the history, the contrast between the appearance of the chest roentgenograms and the patient's clinical condition, the negative tuberculin reactions, the failure to identify bacilli in the sputum, and the negative tuberculin reactions in members of his immediate family, a diagnosis of sarcoidosis was considered. On April 19, 1949, operation was performed.

The gross specimen removed consisted of a mass, 3.0 by 1.7 by 0.7 cm., with some adherent adipose tissue on the surface. Microscopic sections revealed a lymph node with an intact thin fibrous capsule. In some areas were scattered germinal centers, which appeared normal. Irregularly distributed throughout the lymphoid tissue were tubercle-like structures, which varied in size from a single tubercle to groups of six to eight tubercles, none showing caseation necrosis. In many of these were one or more multinucleated giant cells. In the reticular tissue of the node and in several tubercles there were scattered eosinophils, and within epithelioid cells of some areas there was granular brown pigment. Diagnosis was Boeck's sarcoid of a lymph node. Figure 2 shows the typical microscopic appearance.

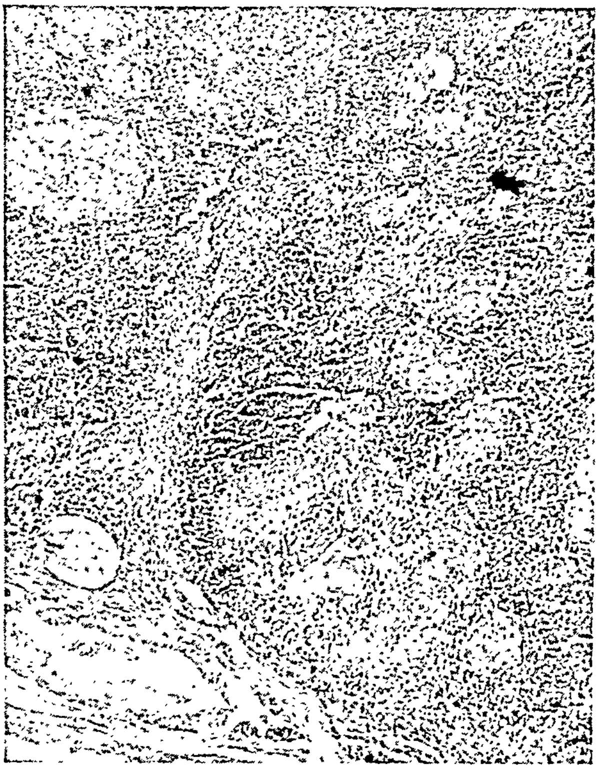

Fig. 2.—A microscopic section of lymph node.

OPERATIVE TECHNIQUE

The surgical technic employed in obtaining the biopsy specimen is essentially the same as the procedure used in doing a phrenic nerve crush. A short horizontal incision is made 1 fingerbreadth above the clavicle, extending laterally from over the lateral border of the sternocleidomastoid muscle. The incision is carried downward by blunt dissection, the lateral border of the sternocleidomastoid being retracted medially, to the scalenus anticus muscle. The scalenus anticus is then freed medially and dependently, thus exposing a space filled by a fat pad, from which the biopsy specimen is taken.

Anatomically the fat pad contains lymphoid tissue which is part of the mediastinal drainage system. If the lymph nodes are not visible grossly or palpable, a generous portion of the fat pad is removed for histological study. On the other hand, as in the case reported, the fat pad space may be filled by a large, solitary lymph node which can be freed and delivered with ease.

SUMMARY

We have presented a case that we consider to be an instance of pulmonary sarcoidosis and have illustrated a procedure that may be of assistance in establishing the diagnosis of this and other intrathoracic conditions.

HYPERVITAMINOSIS A WITH INFANTILE CORTICAL HYPEROSTOSIS

Irving E. Rineberg, M.D., New Brunswick, N. J.
and
Robert J. Gross, M.D., New York

In recent years, and particularly since the report of Caffey and Silverman in 1945, attention has been directed to what appears to be a new clinical entity found in infants. The disease has been called infantile cortical hyperostosis, or Caffey's disease.[1] At 4 to 6 months of age the patient manifests fretfulness, irritability, loss of appetite. The course is febrile or subfebrile. Painful thickenings of the upper and lower extremities associated with circumscribed, soft tissue areas of induration and swelling develop in the extremities, the head, face and the chest wall. In 1930 Roske [2] reported a closely similar syndrome. An increasing number of cases are being reported in the literature, particularly from large clinics that have reexamined their old files of pediatric films and have failed to find these changes on reevaluation of their earlier studies.[3] The conclusion, therefore, seems justified that physicians are dealing with a relatively new entity and not a condition that was previously overlooked. As the literature dealing with this peculiar generalized affection accumulates, more and more variations of the clinical picture are found, as compared with those originally described by Roske in 1930 and by Caffey in 1945. The case to be reported here is of particular interest for two reasons: (1) The age of the patient having signs and symptoms of infantile cortical hyperostosis was 33 months at the onset of illness, much older than any previous case described in the literature, and (2) the history of the case suggests that hypervitaminosis, although often minimized as a cause, may be the underlying factor.

REPORT OF A CASE

J. Z., a girl, was born Oct. 27, 1946. Delivery was normal, and the infant appeared normal at birth. Development progressed satisfactorily, except that teeth did not appear until the age of 8 months. However, at 2½ years of age she had normal dentition.

From St. Peter's General Hospital, New Brunswick, N. J. (Dr. Rineberg), and the New York Medical College, Flower and Fifth Avenue Hospitals, New York (Dr. Gross).

1. Caffey, J., and Silverman, W. A.: Infantile Cortical Hyperostosis: Preliminary Report on New Syndrome, Am. J. Roentgenol. 54: 1-16, 1945.

2. Roske, G.: A Peculiar Bone Disease in Infancy, Monatsschr. f. Kinderh. 47: 385-400, 1930.

3. Scherman, M. S., and Hellyer, D. T.: Infantile Cortical Hyperostosis, Am. J. Roentgenol. 63: 212-222, 1950.

During the winters of 1948 and 1949 she suffered numerous attacks of tonsillitis and pharyngitis that were treated with sulfadiazine and penicillin. During an office visit in November 1948 the mother remarked that she had noted flaring of the lower ribs and beading at the costochondral junctions. Questioning revealed that about six months prior to this time the dietary vitamin supplement (concentrated oleovitamins A and D, navitol®) had been discontinued. A clinical diagnosis of mild rickets was made, and the mother was advised to administer 5 drops of the vitamin preparation daily. The subsequent course of the child was apparently uneventful. On April 30, 1949, tonsillectomy was performed. Recovery was normal.

The child was not seen again until August. At that time the mother stated that she had noted swelling in and about the child's left ankle, particularly on the outer side, for two days, and that the child had complained of pain in this region and walked with a limp. Physical examination revealed only diffuse soft tissue swelling in the region of the left ankle joint. The swelling was thought to be post-traumatic, and conservative treatment was advised. The child was seen again September 12, because the pain and limp had not improved and a hard mass had become apparent on the outer side of the left leg. The child during this period had become intensely irritable. The mother had also noted soft tissue swelling of both wrists and a dusky appearance of the overlying skin. The child experienced pain on movement of the wrists and refused to pick up objects or cried when using a spoon. A swelling was present in the mandibular region of the face, and circumscribed, tender soft tissue lumps were present on the calvarium. On September 12 a roentgenogram of the left ankle (fig. 1) revealed an area of subperiosteal calcification at the lateral aspect of the distal end of the shaft of the fibula and an accompanying swelling of the adjacent soft tissues. A circumscribed soft tissue swelling was also seen in the region of the posterior triangle of the ankle. In the differential diagnosis trauma, tumor and inflammatory change were considered. During the succeeding three weeks the child was followed clinically and was observed to have frequent nose bleeds and tender elevations on the right side of her nose, the lateral surfaces of both knees and the metatarsal region of the right foot. Roentgenographic studies revealed areas of subperiosteal calcification along the margin of the left fibula and the left ulna, as well as thickening of the mandible (fig. 2). She was hospitalized October 1, and biopsy of the left fibula was performed. The incision was carried down to the periosteum, where thickening and elevation of the bone were detected. A small segment of bone extending to the medullary cavity was removed. Microscopic examination showed a strip of newly formed, poorly calcified bone of coarse fibered structure such as is usually seen in ordinary productive periositis.[4] The marrow spaces were filled with fibrous marrow containing thin walled blood vessels and many osteoclasts. Much osteoblastic activity was seen along the bone surfaces (fig. 3). Pathological diagnosis was "productive periostitis."[5]

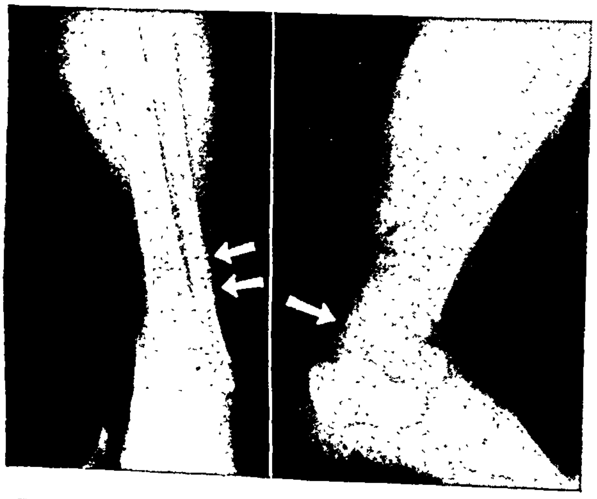

Fig. 1.—Left ankle showing area of subperiosteal calcification at the lower end of the shaft of the fibula with soft tissue swelling.

She was readmitted to the hospital October 17. She had become extremely irritable, lacking in appetite and unable to sleep. Routine laboratory studies showed the blood count to be essentially normal, hemoglobin 89 per cent, red blood cells 4,770,000 and white blood cells 7,500, with a differential of polymorphonuclear leukocytes 57 per cent, lymphocytes 42 per cent and monocytes 1 per cent. The smear was normal. The Mazzini and agglutination tests for typhoid, paratyphoid, Brucella and Proteus OX_{19} were negative. The urine was normal. She was given 40,000 units of streptomycin every four hours, and her temperature, which ranged on admission between 100 and 101 F., gradually subsided within the next six days. When the child left the hospital the irritability was less pronounced. She improved gradually thereafter and in March 1950 was completely free of symptoms. Some thickening of the leg and small, well-circumscribed, soft tissue elevations, were still noted over the base of the nose and over the calvarium (figs. 4 and 5).

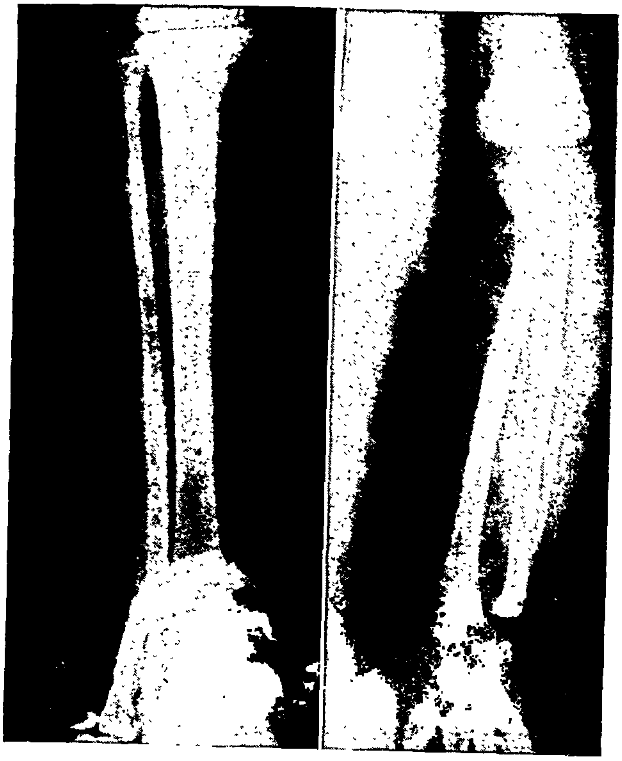

Fig. 2.—Roentgenograms of the left leg and left forearm showing extensive subperiosteal calcificatons.

COMMENT

The demonstration of subperiosteal calcifications involving a number of the long bones, correlated with the patient's clinical appearance, suggested the syndrome described as "infantile cortical hyperostosis." Although age of onset up to 18 months had been reported in the literature, the present case is noteworthy in the fact that the onset of the disease occurred when the child was 33 months old. Subsequent questioning of the mother revealed one other interesting fact. In November 1948 when the clinical suspicion of mild rickets had been entertained, 5 drops of navitol® daily were advised; however, the mother, desiring to make up the deficiency of vitamin D quickly, gave the child 1 teaspoonful of the vitamin preparation daily. This had been continued from November 1948 until August 1949, a period of nearly nine months. On recalculation it was determined that the child had received 185,000 units of vitamin A and 37,500 units of vitamin D daily.

---

[4] Dr. H. Jaffe of the Hospital for Joint Diseases, New York, reviewed the roentgenograms and slide and thought them characteristic of infantile cortical hyperostosis.

[5] Pathological studies were made by Dr. Sylvan Moolten, Director of Laboratories, St. Peter's Hospital, New Brunswick, N. J.

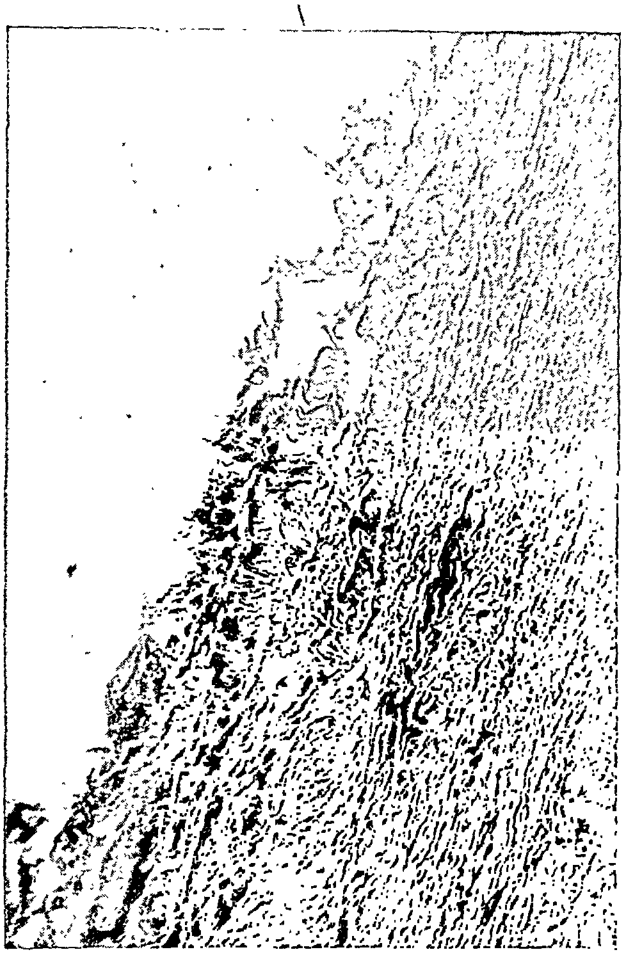

Fig. 3.—Photomicrograph of biopsy specimen showing productive periostitis.

The marked overdose of vitamin A and vitamin D is of particular interest in view of recent reports in the literature of a disease complex caused by overdose of vitamin A, which has many signs and symptoms in common with infantile cortical hyperostosis. Toomey[6] reported a 23 month old infant with bone changes similar to those found in the aforementioned case. Blood studies in this infant revealed a marked increase in the vitamin A level. The child recovered spontaneously after vitamin A was withheld. With the mother's permission, an experimental attempt to reproduce the clinical symptoms was made after the child's recovery. He was given an increased dose of vitamin A utilizing a preparation containing both A and D. The original symptoms and signs recurred. In order to rule out the possibility of vitamin D being responsible for the changes the experiment was repeated utilizing only vitamin A. This too caused recurrence of symptoms and signs.

Rothman and Leon[7] have reported two cases of hypervitaminosis A with characteristic bone changes. In their differentiation between hypervitaminosis A and infantile cortical hyperostosis they mention the age of onset, involvement of the mandible with periosteal thickening, discrepancy between the length of time of increased vitamin administration and the amount of periosteal thickening. In hypervitaminosis A the periosteal thickening in the cases they reported was slight compared with that noted in infantile cortical hyperostosis, and there was no suggestion of lamellation. In animal experiments Wolbach[8] and others have demonstrated marked effects from hypervitaminosis A and avitaminosis A in the growth and development of bone.

Another factor that has recently emerged from the literature is the occurrence of a familial tendency. Boyes and Demy[9] have described two instances in siblings and have referred to three occurrences in one family as reported by others.

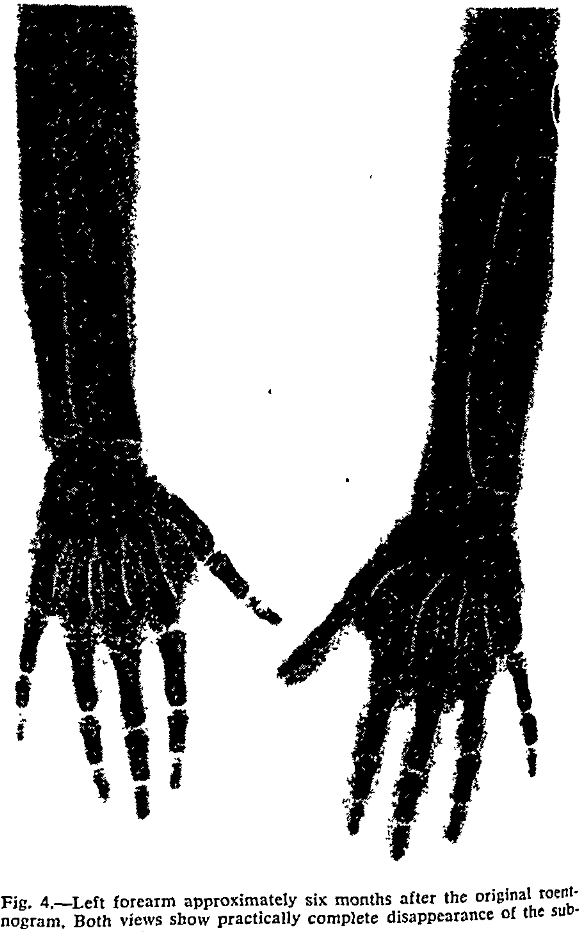

Fig. 4.—Left forearm approximately six months after the original roentgenogram. Both views show practically complete disappearance of the subperiosteal calcifications.

On the basis of these reports it appears we are dealing with a relatively new entity that, although at first confused with scurvy or syphilis, shows distinct differences. The inception of the disease historically coincides roughly with the era of increased vitamin intake in infant feeding. The occurrence of the disease in more than one member of the same family has been shown in certain instances.

[9] Boyes, J., and Demy, N.: Infantile Cortical Hyperostosis: A Familial Disease, Am. J. Roentgenol., to be published.

Animal experiments as well as clinical observations have correlated increased intake of vitamin A with certain soft tissue and bone changes. In the aforementioned case the clinical picture could not be differentiated from infantile cortical hyperostosis. The bone changes and the changes in the mandible and soft tissues were characteristic of infantile cortical hyperostosis. Improvement was dramatic after cessation of vitamin A intake. In addition to age, factors of individual or familial susceptibility to hypervitaminosis A may be important.

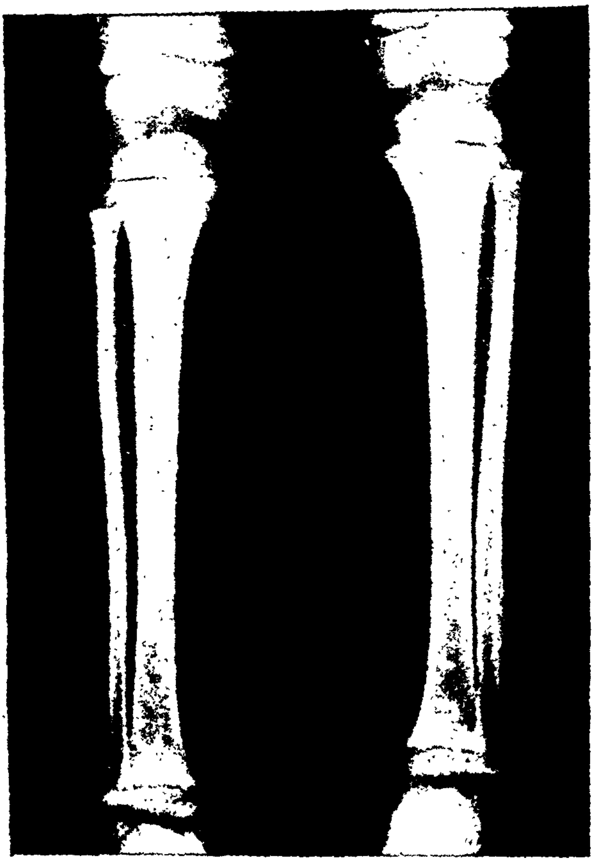

Fig. 5.—Left leg approximately six months after the original roentgenogram. Both views show practically complete disappearance of the subperiosteal calcifications.

Definite correlation between vitamin A overdose and this syndrome awaits the result of vitamin A balance studies.

CONCLUSION

A case is described in which the typical signs and symptoms of infantile cortical hyperostosis developed at the age of 33 months with history of excessive vitamin A intake.

Public Relations.—Every time you look at yourself in a mirror, you should be reminded that, for your patients, you are the medical profession. Your concern for their welfare, your self-sacrificing service to them, and your ethical relations with your colleagues will have more weight with your public than full-page advertisements in every newspaper in the country. It is up to you, not to the professional public relations experts hired by medical organizations, to interpret the views of the medical profession to the public, and to prove to them our sincere desire to give them the best medical care possible under any conditions. —A. M. Phillips, M.D., The Physician's Responsibility, *Journal of the Medical Association of Georgia*, April, 1951.

SUCCESSFUL TREATMENT OF DERMATITIS DUE TO CHRYSOTHERAPY WITH ADRENOCORTICOTROPIC HORMONE

Charles LeRoy Steinberg, M.D.
and
Andries I. Roodenburg, M.D., Rochester, N. Y.

The fact that both adrenocorticotropic hormone and cortisone cause a remission of rheumatoid arthritis in nearly every instance in which they are employed has been most encouraging to those treating the disease. No known previous medication could be so successfully used. However, it is becoming a well-known fact that neither of these two hormone substances cure rheumatoid arthritis. They dampen without extinguishing the fire. No such spectacular results are obtained with chrysotherapy. Complete remissions in well-established cases of rheumatoid arthritis with gold treatment occur in about 20% of treated persons. The remission, if it is obtained, is much more permanent than that with the hormone preparation. Chrysotherapy will be continued in the treatment of rheumatoid arthritis because of these facts. Also if gold therapy is continued, then the various complications associated with its treatment will be encountered. The most frequent complication of gold treatment is dermatitis. The following is a case of gold dermatitis due to chrysotherapy that was successfully treated with adrenocorticotropic hormone.

REPORT OF A CASE

Mr. A. E. S., 41, was first seen April 3, 1950, at which time he complained of painful swollen hands. He first began to have pain in the shoulder joints in the summer of 1949. At that time he was unable to raise his arms. Painful swelling developed in the small joints of the hands, wrists, and knees during the winter of 1950. At first the joint symptoms were migratory but later became localized within the joints. His past history revealed that he had had jaundice some years ago. The tonsils were removed during childhood.

Physical examination revealed a well-nourished white man whose nude weight was 189 lbs. (85.7 Kg.), height 5 ft. 11 in. (180.34 cm.), temperature 98.2 F., pulse 80, and blood pressure 120/80. The pupils reacted to light and accommodation. The teeth appeared normal, but roentgenograms were suggested. The tonsils were absent, and the posterior pharynx seemed normal. Examination of neck, lungs, heart, and abdomen revealed no abnormalities. External genitalia were normal. The prostate was normal in size and consistency. There was soft tissue swelling of the third and fifth right and the first and fifth left proximal interphalangeal joints and the third left metacarpophalangeal joint. There was swelling of the right infrapatellar bursa. The deep reflexes were equal and active, and the vibratory sense was intact.

Urinalysis was normal except for a heavy trace of sugar. Red blood count was 5,200,000; hemoglobin 14.2 Gm.; white blood count 10,500. Differential count revealed stab cells 2%, segmented cells 65%, lymphocytes 23%, monocytes 5%, and eosinophils 5%. The sedimentation rate was increased to 21 mm. per hour. The blood uric acid was normal at 3.4 mg. per 100 cc. Throat culture revealed 75% Streptococcus viridans organisms. Electrocardiogram was normal. Roentgenograms of the hands

---

Director of Arthritis Clinic, Rochester General Hospital (Dr. Steinberg).

taken March 18, 1950, showed a distinctly decreased joint space in the fifth left proximal interphalangeal joint. Antistreptolysin titer was 400 units. Wassermann test was normal. Diagnosis of rheumatoid arthritis was made.

He was placed on 25 mg. of gold sodium thiomalate (myochrysine®) intramuscularly at weekly intervals. The sedimentation rate on May 17, 1950, was 38 mm. per hour and on June 28, 1950, was 20 mm. per hour. There was general improvement in the joint symptomatology on June 28, 1950. There was 50% less swelling noticed in the right knee joint. Gold treatment was stopped on June 21, 1950, because of an itchy sensation on both forearms and over the dorsum of both hands. He was next seen Aug. 16, 1950, and had had no gold treatment since June 21, 1950. On this date red blood count was 4,860,000; hemoglobin 14 Gm.; white blood count 7,900. Differential count was as follows: stab cells 3%, segmented cells, 52%, lymphocytes 31%, monocytes 4%, eosinophils 10%, and basophils 1%. The platelet count was 295,000 per cu. mm. Bone marrow aspiration revealed megakaryocytes, normal erythropoiesis and myelopoiesis, but pronounced eosinophilia. There were 4 to 8 eosinophils per high power field. The sedimentation rate had dropped to 14 mm. per hour. Skin itching was still present, but no rash was noted. All joint swelling had disappeared, but he still had some pain in several of the major joints, particularly the right wrist. He was next seen Sept. 19, 1950, at which time he reported that he had a rash on his legs, forearms, back, and thighs of one week's duration. It was interesting that his last gold treatment was on June 21, 1950. On September 19, his blood studies were as follows: red blood count 5,110,000; hemoglobin 15.6 Gm., and white blood count 7,650. Differential count revealed stab cells 2%, segmented cells 53%, lymphocytes 24%, monocytes 6%, eosinophils 14%, and basophils 1%. The sedimentation rate was normal at 13 mm. per hour. The platelet count rose to 325,000 per cu. mm. Because of the extensiveness of the rash due to gold therapy (fig. 1), he was admitted to the Rochester General Hospital, and adrenocorticotropic hormone was started.

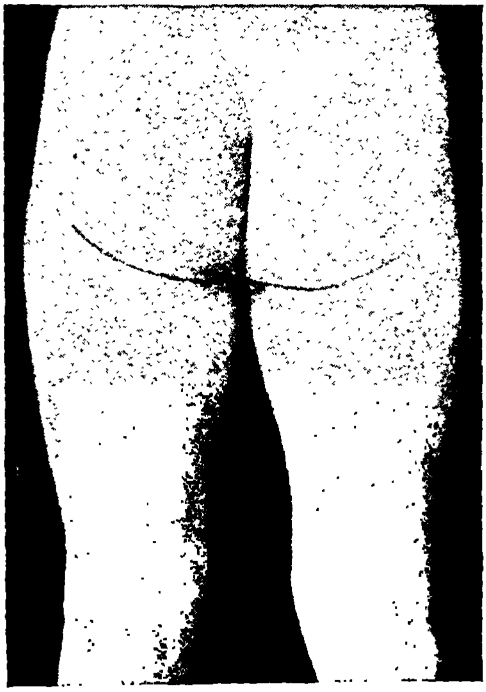

Fig. 1.—Dermatitis due to gold therapy before treatment with adrenocorticotropic hormone.

Photographs were taken immediately of the rash, and then he was placed on 15 mg. of adrenocorticotropic hormone every six hours. Only slight response was obtained to the degree of erythema of the skin rash, and so on Sept. 22, 1950, adrenocorticotropic hormone was increased to 20 mg. every six hours and the patient was kept on this dose until Sept. 29, 1950. Two days after this higher dosage was started, the skin rash began to fade noticeably. The redness of this rash had faded 50%, and the raised surface had disappeared. There was only slight improvement in the degree of itching. On Sept. 24, 1950, itching was considerable, and there was little change in the rash. We thought of discounting adrenocorticotropic hormone and giving dimercaprol (BAL) instead. However, there was subsequent and progressive improvement in the rash, and by Sept. 29, 1950, the rash had completely disappeared, but skin itching remained resulting from unusual dryness following the rash (fig. 2). On the latter date (September 29), the dosage of adrenocorticotropic hormone was gradually decreased as follows: 15 mg. every six hours for four doses, 10 mg. every six hours for four doses, 5 mg. every six hours for four doses, then 5 mg. every 12 hours for two doses. At this point adrenocorticotropic hormone was discontinued. The patient was observed for two more days and was discharged from the hospital when the rash did not reappear.

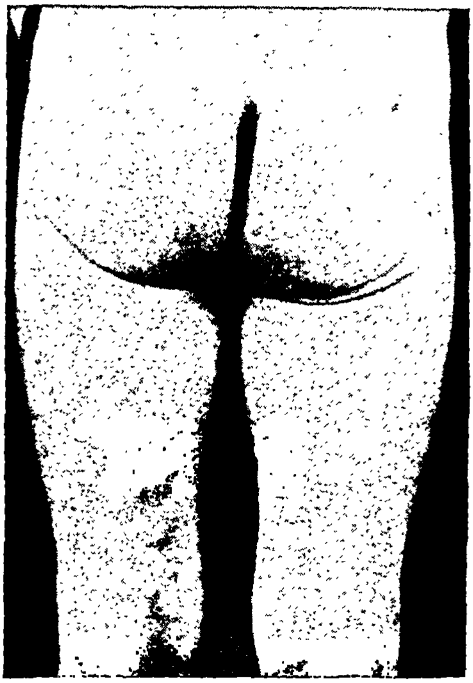

Fig. 2.—Complete disappearance of rash due to gold therapy after nine days of adrenocorticotropic hormone treatment. Skin has residual dryness and slight scaling.

These laboratory studies were done, and the following results were obtained: On Sept. 21, 1950, red blood count was 5,700,000; hemoglobin 16.8 Gm., and white blood count 6,700. Differential count indicated stab cells 6%, segmented cells 52%, lymphocytes 27%, monocytes 9%, and eosinophils 6%. Urinalysis was normal. Blood serology revealed no abnormalities. On Oct. 2, 1950, blood chlorides were 470 mg. per 100 cc., fasting blood sugar 84 mg. per 100 cc., and sedimentation rate 16 mm. per hour. On the same date, blood sodium was 147 mEq. per liter (338 mg. per 100 cc.) and blood potassium 4.1 mEq. per liter (16 mg. per 100 cc.).

SUMMARY AND CONCLUSIONS

Adrenocorticotropic hormone was successful in the treatment of extensive dermatitis due to gold therapy. This hormone treatment is more effective and certainly more pleasant than dimercaprol for this condition.

Medical Arts Bldg., 277 Alexander St. (Dr. Steinberg).

PIPEROXAN HYDROCHLORIDE (BENZODIOXAN) TEST

REPORT OF A FALSE POSITIVE REACTION

Virgil A. Place, M.D., Chicago

The response to piperoxan hydrochloride (benzodioxan) was first described as a diagnostic test for patients with sustained hypertension associated with pheochromocytoma in THE JOURNAL in 1947.[1] Since that time, the test has been generally accepted. The rational use of this drug is based on its specificity for blocking circulating epinephrine, arterenol (norepinephrine) or related compounds. Patients with hypertension of other than the above origins have shown either no alteration or an elevation of the blood pressure when piperoxan hydrochloride has been given intravenously.[2] There have been three cases reported of patients who demonstrated a normal response to the piperoxan hydrochloride test and were later shown to have pheochromocytomas.[2d]

I have been able to find only one case of an unautopsied patient who was reported by Taliaferro to have false positive tests.[3] The diagnosis of renal hypertension in this case, however, has been questioned.[2d]

The case reported here is of interest because of the unusual results of several piperoxan hydrochloride tests.

REPORT OF CASE

History.—J. G. S., a 25 year old white, married college student, entered the hospital on Aug. 14, 1950, as a possible candidate for therapy with an artificial kidney. Seven years before admission, while in the United States Navy and stationed at Chicago, he was diagnosed as having scarlet fever but at the time had no known complications. Two years later, while still in the Navy, he had one episode of painless gross hematuria. He was hospitalized for a single day. One year later, in 1946, he suffered another episode of hematuria, associated with infectious mononucleosis, for which he was hospitalized three weeks. The patient knew of no abnormality of his urine or blood pressure after this, until November 1949, at which time, after an episode of nausea, vomiting, and frontal headache, he was found to have a systolic blood pressure of 250 mm. of mercury. He progressed to a state of coma, but, after three weeks of hospitalization, recovered sufficiently from the episode of encephalopathy to return to college. Subsequently, he was relatively free of symptoms until the week prior to this admission, when he suffered a recurrence of the nausea, vomiting, and headache.

In the physical examination given at admission, the patient's temperature was 99 F.; pulse, 92; respirations, 20; blood pressure, 240/130; weight, 154 pounds. He was a young, thin, white, well developed, alert man, who appeared chronically ill. He hiccoughed frequently but had no dyspnea nor orthopnea. Although he complained of generalized pruritus, he had no dermatitis or icterus. His throat showed no remarkable abnormality, and no lymphadenopathy was present. The optic fundi showed marked spasm, increased light reflex and blurred disc margins without exudates or hemorrhages. His heart was not enlarged, the sounds were loud, and no cardiac murmurs were heard. The abdomen was soft, the kidneys were not palpable, and a nontender liver edge was felt at the costal margin, with no other masses noted. There was no anasarca, peripheral swelling or ankle edema.

Laboratory examinations revealed a hematocrit level of 34 per cent; the hemoglobin was 11.5 Gm., with a red blood cell count of 3,570,000. The white cell count was 7,300, with a normal differential distribution. The Kahn reaction was negative. The urine had a specific gravity of 1.005 and contained protein (4 +). The sediment contained 2 to 10 white cells, 12 to 20 red cells, and 2 to 5 hyaline and cellular casts per high powered field (in centrifuged specimen). The phenolsulfonphthalein excretion was 10 per cent in two hours. Chest x-rays showed cardiac and pulmonary shadows within normal limits. The electrocardiogram showed evidence of left ventricular preponderance. The venous pressure was 210 mm. of saline, with a normal hepatojugular reflex. A circulation time with ether was 15 seconds, and with dehydrocholic acid (decholin®), 23 seconds. His blood nonprotein nitrogen was 78 mg. per 100 cc. and the carbon dioxide, 25.2 milliequivalents per liter. A test made with amobarbital (amytal®) sodium on the second day of admission, with a dose of 0.4 Gm. orally, produced a rise in blood pressure from 200/140 to 220/160 mm. of mercury in three hours.

Within 24 hours after admission, the patient became disoriented, semistuporous and nonresponsive. He was given 16 Gm. of magnesium sulfate intramuscularly in the ensuing 24 hours, and several infusions of 50 per cent dextrose intravenously. His mental status improved to the point of his responding upon hearing his name, and he seemed to regain his appetite, although eating caused nausea and vomiting. A spinal puncture revealed normal cerebrospinal fluid under a pressure of 360 mm.

The following day, disorientation returned and persisted throughout his course. He became incontinent of urine, but peripheral neurological examination remained within normal limits. His temperature spiked to 101.2 F. Grade 3 systolic aortic and mitral murmurs developed within 48 hours after admission; by the sixth day a coarse systolic aortic thrill and fresh retinal hemorrhages were noted. Although five blood cultures taken during these first few days remained sterile, in view of a persistent hyperpyrexia and the changing cardiac murmurs he was treated with penicillin procaine for aqueous injection, 3,000,000 units a day, but without change of status. Although the fluid intake and output remained high throughout his course, the uremia became increasingly severe.

On the fourth hospital day, he was given 0.1 mg. of protoveratrine[4] intravenously over a period of two minutes. The serial blood pressure recordings showed little change in pressure, and no alteration in mental status was noted. The protoveratrine test was repeated on the sixth hospital day, on which 0.15 mg. was administered intravenously; there was a consequent decrease of blood pressure from 206/140 to 190/130. A third trial with this drug, which was given in a dose of 0.18 mg. on the eighth hospital day, produced a decrease in blood pressure from 240/130 to 200/116.

On the sixth hospital day, a piperoxan hydrochloride test was performed. Twenty mg. of the drug, given over a period of two minutes into an intravenous clysis that had been running at least one hour, produced a drop in blood pressure from 240/132 to 220/110 and a return to normal within 8 minutes (fig. 1).

This study was supported by funds from the Otho S. A. Sprague Memorial Institute.

Clinical Assistant in Medicine (Rush), University of Illinois College of Medicine, and Fellow in Medicine and Biochemistry, Presbyterian Hospital.

From the Rush Departments of Medicine and Biochemistry of Presbyterian Hospital and the University of Illinois College of Medicine. Drs. James A. Campbell, George Hass, I. Rochlin, and Henry Tesluk, and Miss Margaret Panos assisted in the preparation of this work for presentation.

[4] Protoveratrine was furnished through the courtesy of E. Meilman, M.D., Beth Israel Hospital, Boston.

Because of the suggestive results of this test, the following morning it was repeated and the same technique was used. A drop in blood pressure from 240/140 to 182/108, with a return to normal 10 minutes after cessation of administration, was observed. Because of these two responses, a third test was planned. It was decided to try to maintain the decreased pressure by intermittent administration of piperoxan hydrochloride. After a total dose of 80 mg. had been given in a period of 20 minutes, with a drop in blood pressure from 240/138 to 158/72, marked cerebral stimulation developed in the patient, resulting in thrashing movements of his arms, attempts to sit up, retching, and moaning; therefore the drug was stopped.

The following morning the test was again repeated, the standard technique being used, and there was a fall in blood pressure from 220/130 to 206/118.

By the ninth hospital day, the blood nonprotein nitrogen was 156 mg. per 100 cc., chlorides were 79, and carbon dioxide 3.5, milliequivalents per liter; phosphorus, 114.8 mg. per 100 cc.; sodium, 125 milliequivalents per liter and potassium, 3.0 milliequivalents per liter. Urinary excretion throughout hospitalization averaged 1,770 cc. a day, with specific gravities ranging from 1.005 to 1.017 and protein contents of 4 Gm. a day. Phenolsulfonphthalein excretion through a retention catheter was less than 5 per cent in two hours, with a volume of 340 cc. When 8.9 Gm. of sodium chloride was given intravenously, 6.1 Gm. was excreted in the next 24 hours. Fluid intake throughout hospitalization averaged 2,590 cc. a day and was maintained by intravenous infusions consisting mainly of 20 per cent dextrose

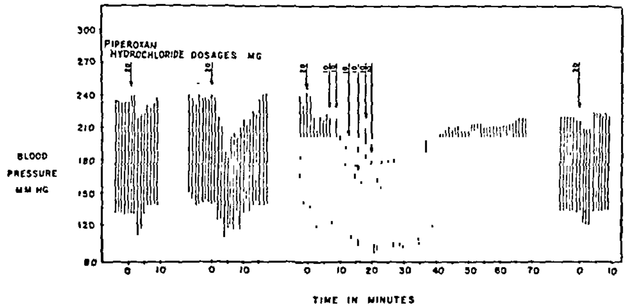

Fig. 1.—Composite graph of the piperoxan hydrochloride tests done during a period of 48 hours.

Because of the marked, yet variable, response shown to the piperoxan hydrochloride tests, and in spite of the terminal state, a perirenal air insufflation was undertaken, but no adrenal tumor was seen. The final two days of the illness were accompanied with progressive increase in temperature and deepening coma, and the patient died on his twelfth hospital day.

Autopsy was performed four hours after death. The heart weighed 519 Gm. There was generalized myocardial hypertrophy. The valves appeared normal. No evidence of pericarditis or bacterial endocarditis was found. The lungs showed an aspiration pneumonia that was most pronounced in the lower lobes.

The right kidney weighed 140 Gm. The left kidney, of similar size, was surrounded by a layer of recently clotted blood that was 4 cm. thick. This hemorrhage apparently had occurred as a result of the perirenal air insufflation done the day before. The capsule of each kidney was tightly adherent and, when removed, revealed a granular, yellowish-brown surface. The findings on section and microscopic examination were typical of an active chronic glomerulonephritis with marked arteriolosclerosis. Few normal glomeruli remained. Most were completely fibrosed. Capsular proliferation was conspicuous. There was a prominent degree of interstitial fibrosis and infiltration with chronic inflammatory cells, especially in the cortical regions, with small, focal abscesses in the medullary portion. The vessels were normal, except for hyalinization of the smaller arterioles (fig. 2).

The adrenals were normally located, the right weighing 6.8 Gm. and the left, 8.5 Gm. They were not irregularly shaped or abnormal in color. No tumor was found. Microscopic examination showed a few focal areas of hyperplasia in the cortex. The medullary-arteriolar system showed a remarkable degree of hyalin thickening of the walls, with an exaggerated endothelial proliferation. In places, necrosis of arterioles had led to local reparative reactions of an unusual type (fig. 3).

No extra-adrenal chromaffin tissue could be found, despite a thorough search of the abdomen and thorax.

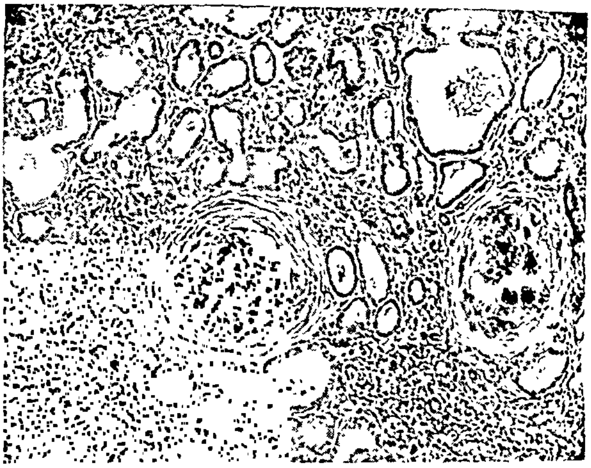

Fig. 2.—Photomicrograph of typical renal lesions.

The brain weighed 1,550 Gm., with no evidence of hemorrhage, and no tumor was found on sectioning. Microscopic study showed an extreme degree of advanced arteriolosclerosis throughout the brain.

COMMENT

Four tests with piperoxan hydrochloride were performed within a period of 48 hours, and a total of 140 mg. of the drug was administered. Side effects were noted only when 80 mg. of this drug was given in 20 minutes, and these reactions were a mild degree of cerebral stimulation.

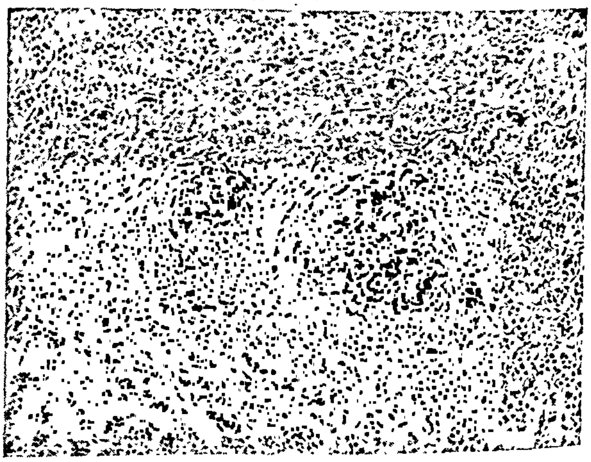

Fig. 3.—Photomicrograph of adrenal medulla, showing severe arteriolosclerosis with necrosis and inflammatory reaction.

Because of a possible cross reaction, no barbiturates were given for 72 hours prior to the piperoxan hydrochloride tests. The extent of fall in blood pressure in the reports of positive piperoxan hydrochloride tests, in patients later proved to have pheochromocytomas, has varied from 22 mm. of mercury, systolic, and 18 mm. of mercury, diastolic, to 120 mm. of mercury, systolic, and

90 mm. of mercury, diastolic. The duration of these responses ranges from 10 to 60 minutes.[5]

In this case, both the duration and the degree of hypotensive response showed wide variation, but by the above criteria all the tests were interpreted as positive. Other patients with essential and renal hypertension have been tested with the same lot of piperoxan hydrochloride used on this patient and have not shown positive reactions.

A definite negative reaction was obtained with the amobarbital sodium test, and there was only a minimal response to large doses of protoveratrine by this patient.

From the time that this patient was first seen, he was in critical condition. His story was consistent with chronic glomerulonephritis, showing marked decrease in renal function, proteinuria and chronic severe hypertension with encephalopathy. His course was one of progressive increase in azotemia, despite adequate caloric and fluid intake and a large urinary volume. Because his primary difficulty was the hypertensive encephalopathy, he was not considered a satisfactory candidate for hemodialysis with the artificial kidney. Although the hypertension was not of a paroxysmal nature, the piperoxan hydrochloride test was performed despite the severe side reactions described by some observers.[6]

The marked variability of the response is a problem, and in the report by Taliaferro [3] the variations showed a progressive decrease, while this case showed no such consistent pattern and the first test evoked a response similar to the fourth.

Because of the apparent false positives reported in piperoxan hydrochloride tests, special care was taken at the autopsy to locate a possible site of excess epinephrine production, but none was found.

The absence of an adrenal tumor and of any abnormal, extra-adrenal chromaffin tissue leaves the cause of the positive piperoxan hydrochloride test unexplained. It is possible that the false positive test has no explanation, but it is worthwhile to emphasize that there was a very severe degree of arteriosclerosis in the adrenal medulla. Ordinarily, in patients with hypertension and generalized arteriolosclerosis, the capsular and subcapsular arterioles show conspicuous changes, but medullary arteriolar disease is generally minimal. Any means by which these changes might alter medullary function and thereby lead to a false positive piperoxan hydrochloride test is unknown.

SUMMARY

A positive piperoxan hydrochloride (benzodioxan) test in a case of chronic glomerulonephritis with hypertensive encephalopathy is reported. The only pathological finding that differed from those generally encountered in other patients with cardiovascular renal disease of similar character was that of the severe arteriolosclerosis in the adrenal medulla. The variation in the response to the drug and the large dose used in one test are discussed. Two other tests of use in the study of hypertension, the amobarbital sodium and protoveratrine tests, gave negative results.

ADDENDUM

Since this paper was submitted, Goldenberg, in his paper entitled "Adrenal Medullary Function," [7] mentioned "four false positives" in which a positive response to benzodioxan was present in cases of hypertensive vascular disease with uremia. No detailed information was included.

WATERHOUSE-FRIDERICHSEN SYNDROME

REPORT OF CURE EFFECTED WITH CORTISONE

L. Roy Newman, M.D., Philadelphia

This pediatric case report is presented for the interest involved in the cure of an apparently hopeless case of an acute and overwhelming meningococcemia and for the therapy instituted.

REPORT OF A CASE

D. M., a 4-year-old white girl, was admitted to the children's pavilion of the Jewish hospital, service of Dr. Robert A. Schless, on Dec. 23, 1950. She had been well until two weeks prior to admission, when she had a severe upper-respiratory-tract infection, from which she recovered completely in a few days. Early in the morning of the day of admission she awoke and was feverish and irritable, and she drowsed all afternoon. By 4 p. m. she was semistuporous. She was referred to this hospital when the attending physician was called and found a generalized petechial rash. On admission the patient was seen to be an acutely ill, semicomatose, lethargic, and irrational child lying limply in bed. A massive petechial and ecchymotic rash was seen breaking out over the entire body. The temperature was 107.5 F., the pulse rate 150 a minute, and the blood pressure 70 mm. of mercury systolic and 40 diastolic. Many subconjunctival hemorrhages were seen. The heart and lungs were normal on examination. The liver was palpable, 1 fingerbreadth below the right costal margin. There was nuchal rigidity 2 + and positive Kernig's and Brudzinsky's signs were elicited. The patient had not voided for six hours prior to admission. A lumbar puncture yielded crystal clear fluid, which contained no cells. The therapy immediately instituted consisted of oxygen, aqueous adrenal cortex extract, a blood transfusion and fluids administered intravenously, sulfadiazine (1½ grains [0.1 gm.] per pound [0.5 Kg.] of body weight) administered intravenously and 1,000,000 units of penicillin in aqueous solution every four hours. The carbon dioxide-combining power was 44 vol. per cent, the serum chlorides 607 mg. per 100 cc., and the blood urea nitrogen 33 mg. per 100 cc.

The blood count showed 37,000 leukocytes, of which 95% were polymorphonuclear.

Within a few hours the blood pressure had dropped to 50 mm. of mercury systolic and 0 diastolic; cyanosis occurred, and the pulse rate rose to 200 a minute. The rectal temperature had fallen to 97 F. Shortly thereafter the patient began to vomit much digested blood and pass tarry liquid stools. She had voided only 30 cc. since admission, six hours before. At that time it was decided to attempt to support and rest the obviously failing adrenals, attempting thereby to reduce the normal vascularity in an effort to abort any active or potential hemorrhage, by giving cortisone intravenously. The patient received 75 mg. immediately and 75 mg. six hours later and then 25 mg. four times daily thereafter for the next three days. By 9 a. m. on the day after admission she responded to

---

From the Jewish Hospital.

some questions and called for her mother. The temperature rose to 101 F., the pulse was 150 a minute, and the blood pressure 75 mm. of mercury systolic and 40 diastolic. She voided 380 cc. of cloudy urine in those nine hours.

Gross hematuria and crystalluria occurred after 24 hr., and the sulfadiazine was discontinued and penicillin continued alone, in conjunction with fluids given intravenously, oxygen, small transfusions, vitamins, and 25 mg. of cortisone which, after the above schedule, was given intravenously twice daily for two days and then once daily for two days.

In 24 more hours the urine was clear, and the temperature was stable at 101 F. The pulse rate was 130 a minute, and the blood pressure was 90/60. The patient was alert, slept soundly at intervals, and voided 1900 cc. on that day. Some edema and fulness of the face were present on the third and fourth days, but these disappeared a few days later. A low-grade fever persisted for a total of five days, but then the temperature dropped to normal. Biotherapy was stopped on Dec. 31, 1950. On Jan. 10, 1951, the patient was discharged, completely well, with only a few petechial crusts on the thighs and legs.

York and Tabor Rd.

METASTASIS TO THE PENIS FROM CARCINOMA OF THE RECTUM

Richard B. Cattell, M.D.
and
Albert J. Mace, M.D., Boston

Malignant involvement of the penis, either metastatic or by direct extension from a carcinoma of the rectum, is exceedingly rare. In a recent review of the literature Thompson [1] found only three cases reported and added one case of his own. In two of the three cases reported the presenting symptom was urinary retention caused by obstruction of the urethra. In the third case the presenting symptom was priapism. Examination revealed metastatic adenocarcinoma of the penis from a primary adenocarcinoma of the rectum in each case. The rectal lesion in these three instances was inoperable, and all three patients were dead from metastatic carcinoma in three to five months. In the fourth case a penile lesion developed subsequent to the resection of the rectum for adenocarcinoma. Priapism was the presenting symptom. This patient died 10 months after amputation of the penis.

Because of the rarity of this condition and the fact that in the previously reported cases no patient has survived over 10 mo., a fifth case is reported. In this case metastatic adenocarcinoma of the penis developed two and one-half years after an abdominoperineal resection for adenocarcinoma of the rectum, and the patient is alive and well nine years after excision of the penile lesion.

REPORT OF CASE

The patient was a 30-year-old white man who complained of rectal bleeding of nine months' duration. At the onset the bleeding was only occasional, but in the later period it occurred with every bowel movement. Proctoscopic examination by a local physician revealed a tumor in the rectum. The pathologist's report on a biopsy specimen was papillary adenocarcinoma, and the patient was referred to the clinic for surgical treatment.

Physical examination findings were normal except for the rectum. There was a fungating rectal tumor 4 cm. in diameter on the left lateral wall, 2 cm. proximal to the mucocutaneous line. The lesion did not appear fixed.

An abdominoperineal resection was performed on Sept. 20, 1938. Abdominal exploration disclosed neither metastases nor extension of the lesion. The lesion was well below the peritoneal reflection, and it was impossible to palpate it from above. When the rectum was freed down to the levator muscles, there was some adherence of the lateral rectal wall to the surrounding tissues but no apparent extension of the tumor into these tissues.

The postoperative course was entirely uneventful, and the patient was discharged, with no complications, on the 22d day after operation.

The pathologist's report was adenocarcinoma, with no blood vessel invasion and eight normal lymph nodes (fig. 1).

From the date of discharge the patient got along very well. The colostomy functioned adequately, and potency was normal. A child was born 18 mo. after the abdominoperineal resection. The patient was able to work and continued to live an entirely normal life. On Feb. 17, 1941, however, he returned to the clinic complaining of priapism associated with severe pain for the past several weeks. Examination findings at that time were entirely normal except for the penis. There was a firm rounded longitudinal mass approximately 5 cm. long and 2 cm. in diameter, on the left side of the penis at the level of the scrotum. This mass was adherent and suggestive of recurrent metastatic carcinoma, even though this was thought to be an unusual site for a metastatic lesion from the rectum. Consequently, the patient was advised to enter the hospital for a biopsy and frozen section study.

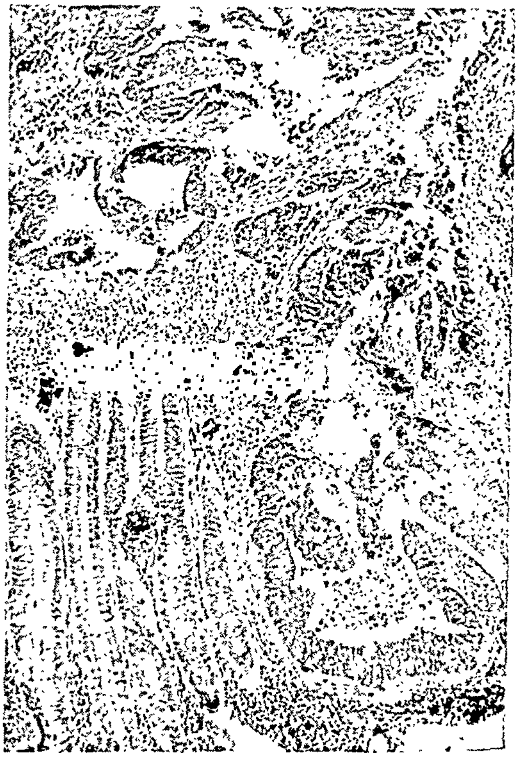

Fig. 1.—Section of adenocarcinoma of the rectum.

At operation, Feb. 18, 1941, the posterior third of the left corpus cavernosum was found to be involved in a hard fusiform tumor mass measuring about 5 cm. long and 2.5 cm. wide. Biopsy and frozen section proved this to be a metastatic carcinoma arising from the rectum (fig. 2). The tumor appeared to involve the right corpus cavernosum at one point. It was necessary to excise both the proximal portion of the left corpus cavernosum and a section of the right corpus cavernosum. A defect remained in the left corpus cavernosum. The postoperative course was uneventful, and the patient was discharged on the ninth postoperative day.

This patient's course has been followed yearly since the last operation. He has been completely symptom-free, with no evi-

---

From the Department of Surgery (Dr. Cattell) and Fellow in Surgery (Dr. Mace), The Lahey Clinic.

[1] Thompson, H. T.: Involvement of the Penis by Carcinoma of the Rectum, Surgery 27:216-220 (Feb.) 1950.

dence of recurrence, for nine years after resection of his metastatic lesion. He has good urinary control; libido and potency are normal. For a few years following the operation during erection the penis would angulate to the left and to the site of the scar. In the past few years this has become almost completely corrected. The patient has no complaints and he carries on an extremely active life.

COMMENT

In the case reported it is difficult to determine whether involvement of the penis occurred by metastasis or by direct extension of the tumor. The fact that the examination failed to reveal any evidence of local recurrence of the tumor in the perineum other than that involving the penis would lead one to believe that it represented a metastatic lesion. Likewise, the fact that the patient has had no evidence of recurrence nine years following excision of the penile lesion is further indication that this was a metastatic lesion.

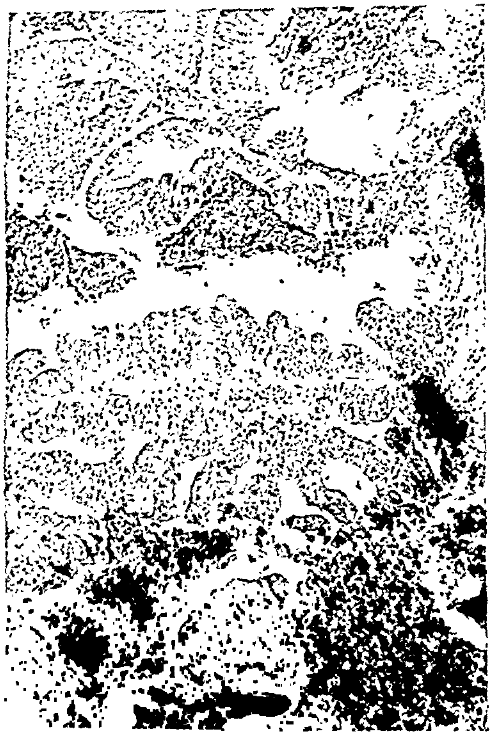

Fig. 2.—Section through the metastatic adenocarcinoma of the corpus cavernosum.

SUMMARY

A case of carcinoma of the rectum secondarily involving the penis is reported. This brings the total number of cases reported in the literature to five.

Priapism, which was the presenting symptom in two of the previously reported cases, was the presenting symptom of the penile lesion in this case.

In only one of the four cases previously reported had resection of the rectal tumor been performed before the appearance of the penile lesion. In this case an abdominoperineal resection had been performed two and one-half years previously.

Three of the patients in the four cases previously reported died within four months, and the other patient died 10 mo. following the appearance of the penile lesion. In this case the patient is alive and well nine years following excision of the penile growth and 11 years after abdominoperineal resection.

MUMPS VIRUS IN HUMAN MILK AND IN MILK OF INFECTED MONKEY

Lawrence Kilham, M.D., Bethesda, Md.

Detection of mumps virus in the milk of a mother with epidemic parotitis at the time of delivery is of clinical interest, as this virus, to my knowledge, has not been hitherto isolated from this source. Mastitis is rarely listed among the manifestations of mumps. As described below, mumps virus was also detected in the milk of a lactating monkey in whom infection had been artificially induced.

REPORT OF A CASE

E. M., a 23 year old Negro woman, was admitted to the hospital[1] on May 2, 1950, for parotitis of two days' duration. She had bilateral swelling and edema in the parotid areas. Mumps had developed in two of her children in the preceding three weeks. Shortly after arrival, the patient was delivered of a full term, normal infant. A sample of milk was obtained three days later at the onset of lactation, when the mother's breasts were engorged and painful. The infant was never breast fed. Its course during the first 3½ weeks of life was considered uneventful.

Laboratory Findings.—Serum specimens for antihemagglutination tests[2] were obtained from mother and infant at delivery and again 24 days later. The mother experienced an eight-fold rise of serum antibody titer from 1:80 to 1:640. No antibodies were detectable in the infant's serums. With the use of methods elsewhere described[3] mumps virus was isolated by inoculation of the mother's milk into the amniotic sac of 7 day old embryonated eggs. The virus appeared on first egg passage and was carried through four further passages. As a check, the virus was then reisolated from the original sample of milk. The agent was identified as mumps virus by antihemagglutination tests with known positive serums. In addition, this virus produced parotitis in a monkey, as described below. Portions of the placenta were ground and inoculated into embryonated eggs. No virus appeared in the course of three egg passages.

EXPERIMENTAL RESULTS

The strain of virus isolated from the patient E. M. and passed five times through eggs was used to induce mumps in two lactating rhesus monkeys (Macaca mulatta). Both monkeys had young of indeterminate age weighing about 2 pounds (907.18 gm.).

Monkey 1.—This monkey received 15 ml. of infected amniotic fluid intravenously. The baby monkey was then kept separate until the mother had been milked the following morning. The mother was milked in similar fashion every two or three days for the next three weeks. No mumps virus was isolated from milk taken in 18 hours and again in three days after inoculation. On the sixth day after inoculation virus appeared on the first egg passage of the milk, as it did from samples obtained on the 8th, 10th and 15th days. Thus the virus was detectable in the monkey's milk over a nine day period. It was not recovered from three subsequent specimens. The mother had no parotid swelling or temperature elevation during the experiment, and her breasts showed no swelling ascribable to mumps infection alone. She had a serum antibody titer of 1:640 by the antihemagglutination test 20 days after inoculation, having had no detectable mumps antibodies prior to this time. The baby monkey failed to show serum antibodies or to manifest any signs of illness.

From the Microbiological Institute, National Institutes of Health, Public Health Service.

[3] Kilham, L.: Isolation of Mumps Virus from the Blood of a Patient, Proc. Soc. Exper. Biol. & Med. 69: 99-100, 1948.

Monkey 2.—Bilateral parotid swelling developed in this monkey seven days after inoculation of Stenson's ducts with mumps virus, and antihemagglutinating antibodies appeared in the serum in a titer of 1:1,280 in the course of convalescence. Milk samples were obtained every two or three days, as in the preceding experiment. However, attempts at virus isolation in eggs were uniformly unsuccessful. As in the case of monkey 1, no detectable serum antibodies developed in the baby monkey, and it never appeared ill.

DISCUSSION

Isolation of mumps virus from the patient E. M. indicates that this agent may appear in human milk in the course of active disease. Presumably this is due to a concomitant mastitis. If such is the case, milk, like saliva, contains virus because it flows from an infected gland. Virus may also pass from the blood stream to the milk without local proliferation. The mumps virus, however, appears to have a predilection for glandular tissue, whether in salivary glands, pancreas or testicle. The fact that orchitis does not occur before the age of puberty suggests that only active testicular tissue is susceptible. By analogy lactating women may be more susceptible to mumps mastitis. The most pronounced signs and symptoms of mumps occur when glands with tough capsules, such as the parotids, and particularly the testicles, are affected. If an inflammatory swelling is not closely restricted, as might be the case in the pancreas or mammary glands for example, mumps infection would have a greater chance of being inapparent. The occurrence of inapparent infections in mumps has been well authenticated by others.[4] Thus mumps mastitis could be overlooked clinically. In the case of the first monkey, mumps virus did not appear in the milk in the hours following a sizeable inoculation of virus. This suggests that in this animal virus did not readily pass from the blood stream to the milk. On the other hand, the appearance of mumps virus in milk specimens taken six to 15 days after inoculation is suggestive of active proliferation in mammary tissue. In the second mother monkey, infection apparently failed to pass from the parotids to the milk.

It is of interest that the infant of patient E. M., in spite of having been in utero while its mother was in an active stage of disease, never gave clinical or serological evidence of mumps. Possibly, infants are not susceptible to mumps infection. To my knowledge, diagnoses of mumps substantiated by laboratory data have not been reported in infants. However, two other explanations are conceivable: first, the mumps virus may have failed to pass the placental barrier in the present instance, and, second, the infant may have been insufficiently developed to have produced a detectable antibody response. Both of the baby monkeys failed to contract mumps, in spite of close contact with infected mothers. It is possible that they also were relatively insusceptible.

SUMMARY

Mumps virus was isolated from the milk of a patient who developed parotitis two days before delivery. The virus was also recovered from milk from six to 15 days after intravenous inoculation of a lactating monkey. Neither the human infant nor the baby monkeys gave clinical or serological evidence of mumps infection.

DEVICE FOR MEASUREMENT OF DIFFERENCES IN HEIGHT OF OPPOSITE SIDES OF BODY

H. Wright Seiger, M.D., Santa Monica, Calif.

A difference in leg length is of importance in many orthopedic and postural examinations. It is measured more accurately in the weight bearing position when the patient is standing erect.

Sighting with one's eyes and hands across the iliac crests or the gluteal muscles provides rough estimates, but these usually are too approximate for accurate measurement. A tape measure, while readily available, is neither accurate nor satisfactory to use on patients in the erect position.

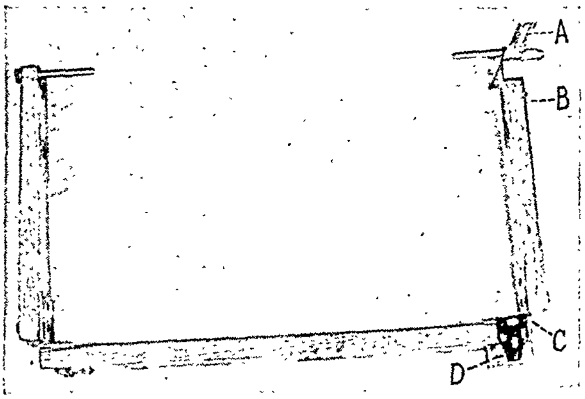

Fig. 1.—Photograph of device for measurement of differences in height of opposite sides of the body. *A*, 6 inch slotted steel rule marked in quarter-inches on inside and half-inches on outside of slot. *B*, set screw. *C*, hinge. *D*, photographer's level.

A rigid fluoroscopic screen[1] with a water level and a wire across the screen is accurate. However, this, besides the expensive apparatus, requires a darkroom and sufficient time for dilation of the pupils, unless a series of cases were being run consecutively.

A simple device that is equally accurate and can be made at a cost of a few dollars is described below. Measurement with this device requires only a few seconds. In addition, with this device, one has a record of the difference in height, which may be especially important in children. It can be used equally well for comparison of the height of the anterior superior iliac spines, greater trochanters, patellas, and shoulders. For the asymmetric, contracted, or arthritic pelvis, comparison of the anterior superior iliac spines is sometimes more accurate than measurement of the tops of the iliac crests, and this comparison also can be more easily done with this instrument. The photographs of the device are self descriptive (figs. 1 and 2).

---

[1] Judovich, B., and Bates, W.: Segmental Neuralgia in *Painful Syndromes*, Philadelphia, F. A. Davis Company, 1944, p. 43.

In practice the left pointer is placed over the left iliac crest, and the right pointer with the metal ruler attached is placed on the right iliac crest. A plus or minus reading is obtained directly. A reading accurate to one-eighth inch can be quickly obtained. The water levels should be checked momentarily beforehand. In an obese patient in whom the iliac crests are not felt distinctly, it might be preferable to mark the edge of the crests with a pencil in advance. The same applies to the anterior superior iliac spines or other parts of the body. If the device is dropped and the hinges are twisted out of shape, it can be quickly recalibrated by a recheck on the edge of a table that is level. The levelness of the table can first be ascertained by placement of the body of the device on the table.

For examiners with defective vision, the set screw at *B* can be tightened with the device on the patient, and a reading made in a strong light after removal of the device from the patient. In the same manner, one can steady the rule *A* with one's finger before withdrawing it to a stronger light. Finally, blocks of different thickness may be placed under the short leg until the difference is rectified. When the anterior superior iliac spines or the patellas are being measured, the patient should face the examiner.

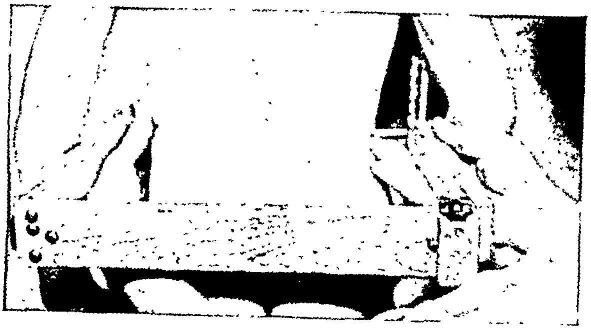

Fig. 2.—Photograph illustrating use of the device.

Made individually, the arms and body of the device can be more easily constructed of hardwood, but commercially, with proper dies, it probably should be made of light metal alloy.

CONCLUSION

The device described above is low in cost. It will give quickly and accurately, to one-eighth inch, a record of the comparative length, when the patient is standing erect, of both sides of the body at various levels and more particularly of the lower extremities.

Vitamin B_{12}.—At last, in 1948, after 20 years of endeavor, the nature of the antipernicious anemia principle was disclosed with the isolation of vitamin B_{12}. The pure vitamin, originally prepared from liver, has been shown to initiate and to maintain complete hematologic and clinical remission in nearly all cases of Addisonian pernicious anemia, quite as do highly purified extracts of liver. Because such effects can be produced by the daily injection of as little as one microgram of the pure vitamin, it is apparently one of the most active pharmacologic agents known. However, presumably because of the lack of the so-called gastric (intrinsic) factor, in most patients with pernicious anemia the daily oral administration of as much as 50 micrograms of vitamin B_{12} is relatively ineffectual.—W. B. Castle, M.D., Present Status of the Etiology of Pernicious Anemia, *Annals of Internal Medicine*, May, 1951.

A TRACTION DEVICE FOR FRACTURES OF THE FOREARM

Walter A. Wichern, M.D.
and
Robert H. Bacon, M.D., New York

Fracture of the lower radius and ulna of the Colles type is the predominant fracture encountered in the emergency service of any hospital. Many cases are complicated by pronounced comminution, displacement or both, so that traction becomes an important factor in reduction. Formerly, traction was applied by an assistant holding the brachium and another holding the hand. Such traction, in many instances, has proved inefficient. It is variable and necessarily of short duration, because the assistants become fatigued. Consequently, manipulation of the fractured elements becomes necessary, and increased trauma results. That efficient and adequate traction is the most important factor in the reduction of fractures has been appreciated for many years. This was particularly emphasized by Böhler.[1] It has been our purpose to provide mechanically a constant, fixed traction for the reduction of fractures of the forearm. This has been accomplished by a modification of an apparatus reported by Caldwell.[2] It has been used by the attending and resident staffs at the Roosevelt Hospital with consistently good results.

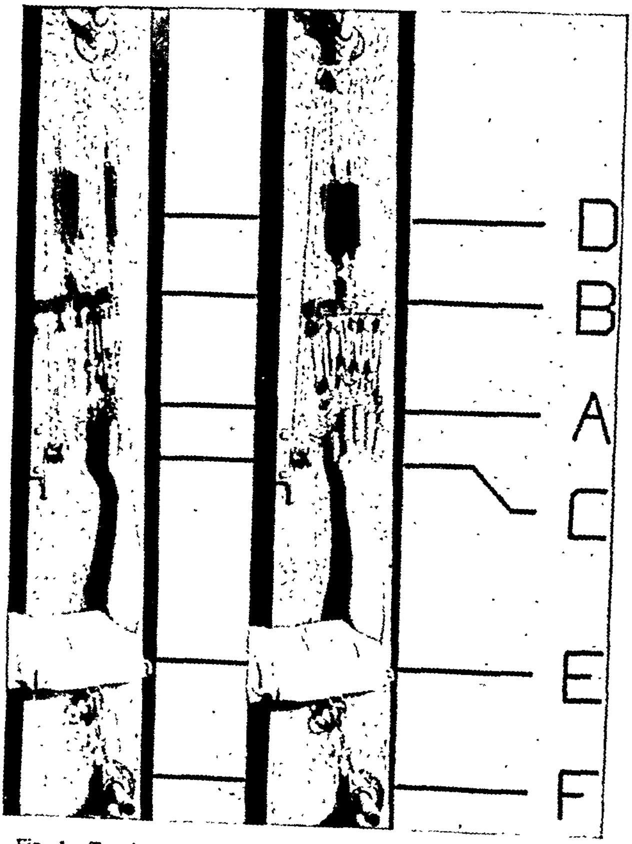

Fig. 1.—Traction Device. *A*, finger traps. *B*, T-bar and pulleys. *C*, winch. *D*, spring scale. *E*, padded canvas sling. *F*, upright pipe.

From Roosevelt Hospital.

[1] Böhler, L.: Treatment of Fractures, ed. 4, Baltimore, William Wood & Company, 1935.

[2] Caldwell, J. A.: Device for Making Traction on the Fingers, J. A. M. A. 96: 1226 (April 11) 1931.

The traction device is demonstrated in figures 1 and 2. The materials for its construction, which are rather easily obtainable, are as follows: plywood base of ¾ by 9 by 63 inches (1.91 by 22.86 by 160.02 cm.), five meshed wire finger traps,[3] a 0 to 50 pound spring scale, two lengths of 1 by 12 inch (2.54 by 30.48 cm.) pipe, two pipe mounts, wire cable, a canvas sling, 10 small pulleys and one large pulley and a winch with a rachet lock. It consists of a series of finger traps (fig. 1) that are fixed to a T-bar (*B*, fig. 1) by a system of pulleys designed to equalize the traction on the individual fingers. Traction is applied by means of a small winch (*C*, fig. 1) and wire cable that passes over a pulley attached to an upright pipe at one end of the plywood base. The amount of traction applied is recorded by a spring scale (*D*, fig. 1) between the T-bar and the wire cable. Countertraction is obtained by a well padded canvas sling (*E*, fig. 1) secured to an upright pipe (*F*, fig. 1) at the other end of the baseboard.

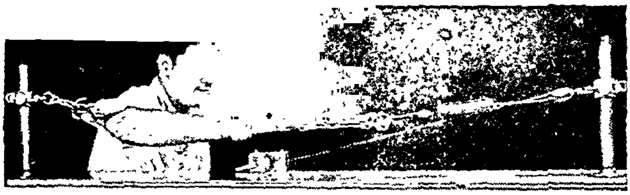

Fig. 2.—Side view of traction device, showing position of patient.

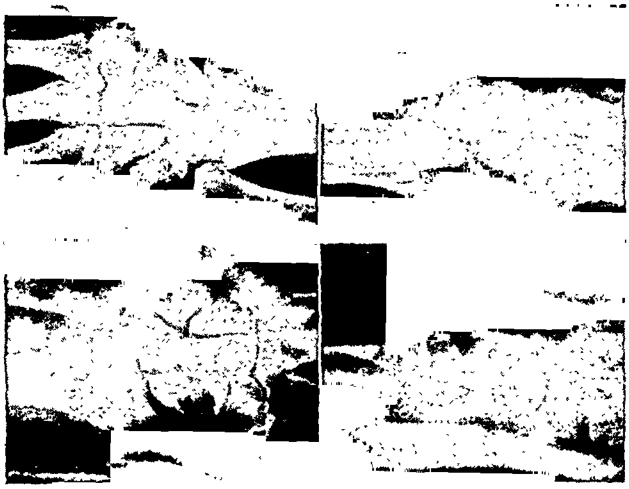

Fig. 3.—Colles' fracture. Upper left: anteroposterior view. Upper right: lateral view. Lower left: anteroposterior view after reduction. Lower right: lateral view after reduction.

The patient is positioned on the fluoroscopy table or sitting at its side (fig. 2). The skin of the hand and forearm is prepared with soap, alcohol-ether and benzalkonium (zephiran®) chloride solutions. Sterile drapes are applied. The hematoma at the fracture site is infiltrated with 10 cc. of 2 per cent procaine solution.[4] During the 10 minute period required for full anesthesia to be obtained, the skin of the fingers is protected with strips of adhesive tape and the finger traps are applied. The arm is placed in the apparatus, with the brachium abducted to 90 degrees and cradled in the canvas sling. The antibrachium is then flexed to 90 degrees, and traction is gradually applied by the winch. For Colles fractures, 18 pounds of traction applied for 10 to 12 minutes has given excellent results. During this period, the fractured elements are distracted and the circumferential force of the relaxed muscles causes them to seek a normal anatomical arrangement. No manipulation is necessary. With the arm still in traction, reduction is checked with fluoroscopy in the anterior-posterior and lateral views (fig. 1) and immobilization is carried out with plaster of paris splints. If desired, ulnar deviation and palmar flexion may be obtained by insertion of a firm roll of muslin, 6 inches (15.24 cm.) in diameter, under the volar aspect of the wrist. Traction is maintained until the plaster of paris splints are firm.

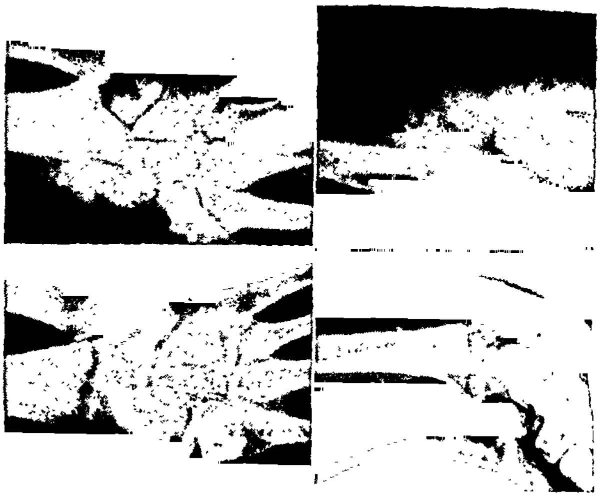

Fig. 4.—Colles' fracture with pronounced comminution and displacement of the distal radial fragment. X-ray views same as in figure 3.

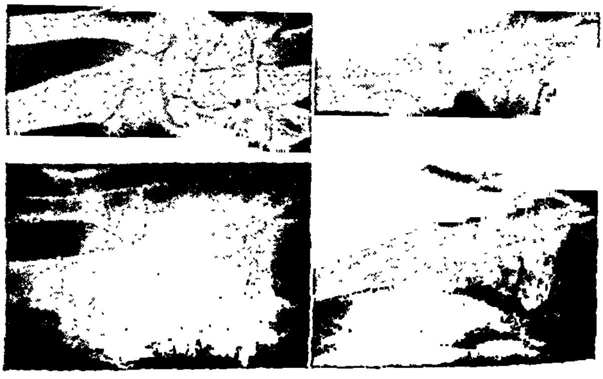

Fig. 5.—Colles' fracture with comminution and dorsal and lateral displacement of the distal radial fragment. X-ray views same as in figure 3.

Figures 3, 4 and 5 demonstrate results of traction applied for a period of 12 minutes. No manipulation was employed. Reduction was accomplished with ease and without additional personnel, who might be otherwise employed. All comminuted and displaced fractures of the radius and ulna are reduced with the traction apparatus. Seventy-five patients have been thus treated, and reduction and immobilization have been easily obtained.

---

[3] The finger traps may be purchased from the Kellems Co., 15 Williams St., Stonington, Conn.

[4] We have found it possible in suitable subjects to reduce badly displaced Colles' fractures by the gradual application of traction without anesthesia. On the other hand, general anesthesia has been employed in apprehensive children.

There has been no difficulty with regard to compression of the fingers as a result of pressure from the finger traps. The device is also useful in the demonstration of the carpal bones, since by their distraction they become individually more prominent. It may also be used to distract metacarpal fractures with consequent reduction prior to their immobilization. Dislocations of the metacarpophalangeal and interphalangeal joints are readily treated. Distraction and reduction may be obtained and maintained for those fractures of the forearm requiring intraosseous fixation. The device is practical and efficient, and no contraindications are offered to its use.

SUMMARY

A traction device for the reduction of fractures of the forearm is described. This device is capable of applying efficient fixed traction, of known amount, which is adequate for the reduction of almost all Colles type fractures without further manipulation. The design and technique of its use and the results are described.

Roosevelt Hospital, 428 59th St. West, New York.

COUNCIL ON PHYSICAL MEDICINE AND REHABILITATION

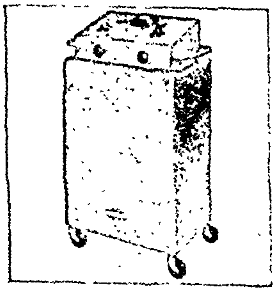
The Council on Physical Medicine and Rehabilitation has authorized publication of the following reports.

Howard A. Carter, *Secretary.*

ALOETRON SHORT WAVE DIATHERMY; MODEL F 8400, ACCEPTED

Manufacturer: A. S. Aloe Company, 1831 Olive St., St. Louis 3.

The Aloetron Short Wave Diathermy, Model F 8400, is a generator of short wave diathermy radiation of wavelength approximately 11 meters, frequency 27.12 megacycles. It is designed for both medical applications and office surgery. It can be moved about on the floor on casters, weighs 50 kg. (110 lb.), and measures 99 by 42 by 62 cm. (39 by 16½ by 24½ in.). Packed for shipment it makes a package weighing 110 kg. (240 lb.) and measuring 135 by 52 by 75 cm. (53 by 20½ by 29½ in.). The foreign shipping weight is 110 kg. Included in these shipping weights are one line cord and two 8 by 10 in. (20 by 25 cm.) pads.



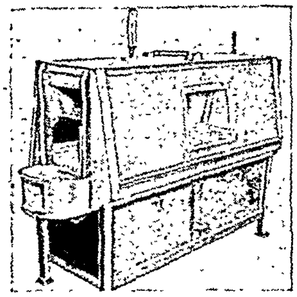
Aloetron Short Wave Diathermy Model F 8400

The Council obtained evidence of satisfactory construction; the performance of the induction cable, induction drum, triple induction drum (three-hinged panels) and cuff electrodes was found satisfactory. It was noted that the device was also furnished with pad electrodes, prostatic and vaginal electrodes, sinus electrodes and a "caput applicator," types of accessories which are not accepted by the Council. Evidence indicated that in phantom load tests the apparatus delivered 200 watts of output with adjustable drums and 155 watts with the cuff electrodes. A statement from Underwriters' Laboratories, Inc., certified that the apparatus had been found acceptable for listing, and a statement from the Federal Communications Commission certified that the apparatus has Type Approval No. D-525. The Council on Physical Medicine and Rehabilitation voted to include the Aloetron Short Wave Diathermy, Model F 8400, in its list of accepted devices with the reservation that pad electrodes, prostatic electrodes, vaginal electrodes, and sinus mask electrodes remain unacceptable because of insufficient evidence to substantiate the therapeutic efficacy of these accessories.

COMMONWEALTH THERAPEUTIC UNITS ACCEPTED

Manufacturer: Commonwealth Sheet Metal Engineering Work, 36 Wall St., Binghamton, N. Y.

The Commonwealth Therapeutic Unit, Model No. 1, is intended for the administration of fever therapy and for the application of heat to large areas of the body. It is a horizontal cabinet large enough to contain a recumbent adult with his head projecting through an aperture at one end. Designed primarily to permit the exposure of the trunk and extremities to warmed, humidified air as in fever therapy, it contains a sprinkler for washing the patient and for flushing the interior of the cabinet. The apparatus measures 241 cm. (95 in.) in length, 127 cm. (50 in.) in height and 86 cm. (34 in.) in width. It weighs about 258 kg. (570 lb.). When crated for shipment it measures 253 cm. (100 in.) in length, 138 cm. (54 in.) in height and 100 cm. (40 in.) in width. The weights are 373 kg. (820 lb.) for domestic and 408 kg. (900 lb.) for foreign shipment. Connections for hot and cold water are required for the waste pipe and for electricity. A window in the front enables the operator to observe the color of the patient's skin, and a porthole makes nursing care possible during prolonged fever treatments. The unit is not recommended for the treatment of obesity. There are two other models, Nos. 2 and 3, which differ only in size.



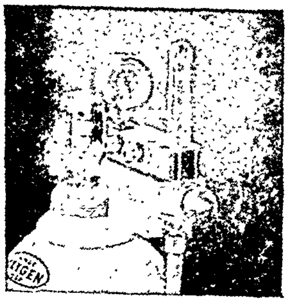
Commonwealth Therapeutic Unit

The Council obtained evidence from acceptable sources that the apparatus was of sturdy construction and that it performed as represented by the manufacturer. The Council on Physical Medicine and Rehabilitation voted to include the Commonwealth Therapeutic Units in its list of accepted devices.

LINDE TYPE R-501 OXYGEN THERAPY REGULATOR ACCEPTED

Manufacturer: Linde Air Products Company, A Division of Union Carbide and Carbon Corporation, 30 East 42nd Street, New York 17.

The Linde Type R-501 Oxygen Therapy Regulator is a device intended for use in the clinical administration of oxygen in the hospital, the clinic, the physician's office, or the patient's home. It bears a gauge to indicate the pressure of the gas remaining in the cylinder and a flowmeter graduated in liters (of oxygen) per minute.



Linde Type R-501 Oxygen Therapy Regulator

The device is small enough to be fastened to and supported by a standing gas-cylinder of the usual 4 or 5 ft. size. It weighs 2.7 kg. (6 lb.). Packed for shipment it makes a package measuring 15 by 30 by 26 cm. (6 by 12 by 10 3/16 in.) and weighing 3.6 kg. (7 lb. 13 oz.). The foreign shipping weight is 3.6 kg.

Evidence was obtained from sources acceptable to the Council that the device was satisfactory for administering oxygen therapy under working conditions in a hospital ward. The Council on Physical Medicine and Rehabilitation voted to include the Linde Type R-501 Oxygen Therapy Regulator in its list of accepted devices.

GRANTS TO MEDICAL SCHOOLS

Those interested in the future of medical education received substantial encouragement on July 19 with the announcement that the National Fund for Medical Education had made its initial distribution of grants totaling $1,132,500 to the 79 medical schools of the country. It is expected that the Fund, with the cooperation of professional, industrial, and civic leaders throughout America, will raise a total of at least 5 million dollars for medical education and that the schools will receive additional grants before the year is over.

The circumstances motivating this effort on the part of medical educators, the medical profession, and many from beyond the field of medicine to raise funds for the medical schools were and are many. The nation's facilities for the education of physicians have been heavily burdened during recent years by the effects of rising costs, reduced income from endowments, and fewer large individual gifts. As each year passed, the problem became more serious. Finally, it captured the attention of national leaders from many walks of life.

Representatives of the medical profession, in company with leaders from America's great industries, education, agriculture, and labor, who were aware of the urgency of needs at the inflation-plagued centers of medical education, met to devise a method of relief. Together, more than two years ago, they formed the National Fund for Medical Education, whose primary responsibility is to raise needed funds from voluntary sources and distribute them to the nation's medical schools. The initial grants signal the first achievement of these goals.

In comparison with the over-all operating budgets of the medical schools, totaling many millions, the National Fund's grants may seem to some small. Four-year schools received $15,000, while two-year schools were given half that amount. However, for many of the schools these grants constitute the largest amount of totally unrestricted money that they have had available in recent years. Consequently, these grants, which each school can use where they are most needed, have for the medical schools a useful value out of proportion to the actual number of dollars involved.

The medical profession is demonstrating its willingness and ability to aid significantly in meeting the problem of the nation's medical schools. Through the American Medical Education Foundation, one of the supporters of the National Fund, the physicians of America have provided more than one-half the total fund just distributed. The profession's activities in support of the Foundation, however, must continue, for it has pledged itself to raise a minimum of a million dollars during 1951.

The goal for 1951 is still unmet, and in a spirit of "first things first," every physician in America is asked to do his part in preserving and strengthening the educational institutions which have made the standards of his profession possible. He can help by giving immediately a contribution to the American Medical Education Foundation. Information on such contributions can be found on Advertising page 15 of this issue of THE JOURNAL.

ASPIRATION OF VOMITUS DURING OBSTETRIC ANESTHESIA

In a recent article Merrill and Hingson [1] call attention to the hazard of aspiration of vomitus during anesthesia in obstetrics. Questionnaires replied to by 183 hospitals reporting a total of 2,503,921 births in the past five years revealed 59 maternal deaths during this period from such aspiration during induction or during emergence from anesthesia. From these figures, the authors estimate that in the United States there must be at least 100 maternal deaths per year from this cause. This would represent some 2% of the total maternal mortality.

Factors that predispose to vomiting during obstetrical anesthesia include a delay in the emptying time of the stomach during labor; a predisposition to anoxia due to limitations of respiratory exchange caused by the enlarged uterus; the light anesthesia that is necessary to maintain uterine contractibility and the cooperation of the patient, but which renders the vomiting center hypersensitive; and the difficulty of achieving proper preparation in the face of certain obstetric emergencies. To reduce the incidence of these seemingly unnecessary deaths, the authors recommend that prenatal instruction include a warning of the danger of eating at home after the onset of labor. In the hospital, food by mouth should be withheld from all patients in active labor. For those patients in rapidly advancing labor who have eaten within six hours, spinal or caudal analgesia should substitute for intravenous or inhalation anesthesia unless the stomach is artificially emptied. Finally, adequate equipment should be readily available in the delivery room for the treatment of vomiting during anesthesia. Recommended therapeutic measures include placing the patient in deep Trendelenburg position, stopping anesthesia to permit return of the cough and laryngeal reflexes, aspiration of food particles under direct bronchoscopic examination, and the administration of 5 to 10% carbon dioxide to produce hyperpnea.

---

INCOME OF PHYSICIANS

The United States Department of Commerce published in its July *Survey of Current Business* an article by William Weinfeld, "Income of Physicians, 1929-49." This is the first report of the results of the survey of the 1949 incomes of physicians in the United States which was a joint undertaking of its Office of Business Economics and the American Medical Association's Bureau of Medical Economic Research. Elsewhere in this issue (page 1249) is a summary and analysis of this first report by Frank G. Dickinson, Director, and Charles E. Bradley, Associate in Economics, Bureau of Medical Economic Research. They have worked closely with Mr. Weinfeld and Mr. M. Joseph Meehan, Director of the Office of Business Economics, in preparing the questionnaires, in selecting the samples, and in the mailing. The tabulations and the interpretations in the Weinfeld article, although presented to Dickinson and Bradley for critical examination prior to publication, are the responsibility of the Department of Commerce. Later the questionnaires will be loaned to the Bureau of Medical Economic Research for further analysis and study.

This survey, in which more than 55,000 physicians participated, is the broadest mail questionnaire survey of professional incomes ever made in the United States. The wide variety of data provided makes it difficult to prepare a short summary. The more important averages are presented in the summary by Dickinson and Bradley. Possibly the most significant general conclusion is found in the third paragraph of Weinfeld's article: "In the 20 year period since 1929, the average net income of all civilian physicians more than doubled, but this relative increase was practically identical with that for all earners in the general population over the same period." Dickinson and Bradley reached the same conclusion regarding changes since the period 1935-1939, a more commonly used base period than 1929 in economic reports. They also call attention to the fact that all averages refer to net income before taxes, and that the gain in net income after taxes in recent years was considerably less. The increases in the earnings of physicians during the past 12 or 20 years have been due to three factors: a moderate increase in fee schedules, better collections, and greater "output per physician."

The average (mean) net income from medical practice of the 30,000 physicians whose returned questionnaires have already been analyzed was $11,058; this net amount was 60.4% of the average (mean) gross income, $18,316. Since 1945 the percentage of the mean net to the mean gross income of nonsalaried physicians declined from 63.3% to 59.6%. The median net income was $8,835; that is, one-half of the physicians reported net incomes of less than this amount and the other one-half reported higher incomes. Many statisticians regard the median income as more descriptive than the mean income in such surveys.

The reactions of physicians to these and the other averages from the survey will vary considerably. Older physicians who have been in practice for many years may consider them too high, while physicians at the earning peak of their lives may regard them as too low. The very large numbers of returns analyzed, 30,000, would seem, however, definitely to establish these averages for the broad groups of physicians.

Weinfeld notes that the evidence is now clear that the average earnings of physicians are above those of lawyers, the reverse of the situation which prevailed one or two decades ago. He also notes that the physicians who are compensated entirely by salary had mean incomes $3,310 lower than those who received no salary, that is, dependent entirely on fees from patients. Dickinson and Bradley attribute roughly one-fourth of this difference to the pension rights of salaried physicians and as much as one-fourth to the value of vacation pay and sick leave benefits.

The mean net income reported by general practitioners in independent practice was $8,835 as compared with $15,014 for full-time specialists. Weinfeld calls attention to the fact that this excess was not as great, percentagewise, in 1949 as it was in 1929—$6,200 and $6,100.

The mean and median net incomes of the nonsalaried physicians were highest in the Far West (Washington, Oregon, Nevada, and California), $14,235 and $12,243. New England ranked lowest in both mean and median incomes, $9,602 and $7,818. The Weinfeld article also presents averages for individual states and named cities. Dickinson and Bradley, however, have some doubts about the statistical validity of some of these averages for particular cities and states and are also somewhat skeptical about the averages for the specialties which ranked neurological surgeons first and pathologists second in both mean and median incomes.

This survey provides good bench-mark data on the incomes of physicians, a subject about which there has been a considerable amount of highly speculative writing and speaking in recent years. Thus the entire medical profession has benefited by the willingness of 55,000 of its members to cooperate with the U. S. Department of Commerce in one of the periodic surveys needed in the preparation of estimates of national income and personal consumer expenditures. The study is replete with evidence that the highest average incomes are not being earned by physicians in the large metropolitan cities. This information should buttress the arguments of the many physicians and lay leaders interested in improving medical care in the smaller cities and towns of the rural parts of the country. Although many factors are involved in the choice of location, this study is commended to all interns and residents who are faced with the problem of choosing a location.

In the larger sense this study demonstrates again that there was no nation-wide shortage of physicians in 1949, for physicians' incomes had risen just about as fast percentagewise as the average income of the American people. The mean and median net incomes in 1949 of physicians would have been far higher if there had been a nation-wide shortage of physicians. On the other hand, this study provides much evidence of the economic advantages of practicing medicine in the small and medium-sized cities and, indirectly, may suggest to some an over-supply of physicians in metropolitan centers.

THE PRESIDENT'S PAGE

A MONTHLY MESSAGE

One of the primary reasons for the organization of the American Medical Association in 1847 was "to elevate the standard of medical education in the United States." Ever since that first meeting, the advancement of medical education has been a continuing major activity of our Association. It is fitting, therefore, that I devote one of the President's Pages to a review of the A. M. A.'s influential role in this field and to a discussion of the profession's responsibility in the training of future physicians.

One of the first acts of the American Medical Association after its organization was the establishment of a Committee on Education. This committee faced a chaotic situation. The westward migration and other unsettled conditions in the United States made the demand for doctors high. Since there were virtually no restrictions on the establishment of medical schools, they were mushrooming rapidly. Most of them were operated for the profit of promoters and faculty, and more attention was given to attracting numbers of students than to the quality of training. While there were a few good schools, most of the remainder ranged from six-month semblances of scientific educational institutions to diploma mills which sold degrees for a fee.

The struggle of the American Medical Association, together with the Association of American Medical Colleges and other groups, to raise the standards of education from this chaos to their present high level provides one of the most brilliant chapters in modern medical history.

During the first 56 years of the Association's existence, many resolutions were passed and the schools were asked again and again to improve their curriculums, with little result. Then, in 1903, the Committee on Education was reorganized as the Council on Medical Education. This strengthened group established "minimum" and "ideal" standards for medical schools, thus giving them specific goals. It also divided the schools into four classes, on the basis of the number of their graduates failing to pass state licensure examinations, and regularly published these tables.

Considerable resentment developed in the medical colleges from these reports. To help offset this, the Council asked the Carnegie Foundation to conduct a study of medical education, the result of which was the famous Abraham Flexner report which illustrated so clearly the deplorable state of the medical schools in the United States. From that time on, the revolution was under way and the poor schools either closed or else improved their curriculums until they received approval. Today all schools in the United States are fully approved by the Council. Its work with medical education, therefore, is now less of a policing action and much more of a counseling and information service.

Meanwhile, the Council on Medical Education had recognized the importance of internships, and in 1912 it undertook its first survey of hospitals. Since 1928 the Council has maintained a staff of trained hospital inspectors who devote full time to improving education standards in hospitals. They not only collect factual data necessary for evaluation but counsel hospitals on ways and means of improving training. This well-recognized consultation service operates without cost to hospitals in the United States.

Another field that attracted the attention of the Council during the second two decades of this century was that of graduate education. Realizing that physicians must continue learning after receiving their degrees, and recognizing the importance of further study in special fields, the Council in 1920 organized 15 committees "to recommend what preparation was deemed essential to secure expertness in each of the specialties." These committees were the forerunners of today's specialty boards, which have developed and now operate with the assistance of the Council.

Other important activities which can be mentioned only in passing are the approval of schools for laboratory technicians, occupational therapists, and other technicians in fields allied to medicine (at their request), the listing of postgraduate medical courses, openings for residencies and internships, and foreign medical schools, and periodic national surveys of medical education.

This brief history shows clearly the important role that the American Medical Association, through its Council on Medical Education and Hospitals, has played in the improvement of medical education. This role has brought it on occasion into conflict with groups both within and without the profession. However, the high regard in which medical education is held today attests to the soundness and integrity of its work.

While continuing the many constructive activities I have detailed above, the American Medical Association is again embroiled in a controversy, this time over federal aid to medical education. There is no doubt that our medical schools need more money. The Association believes, however, that S. 337, the federal aid to medical education bill now before Congress, would inevitably lead to federal control because it provides funds for over-all operating expenses of medical schools—thus putting a finger in every budgetary pie. The Commission on Financing Higher Education also opposed this bill in a recent report, saying that, until it had been demonstrated that other sources of funds were exhausted, no such radical and far-reaching change should be undertaken.

The American Medical Association proposes this two-point program instead: (1) stepped-up raising of voluntary funds through the American Medical Education Foundation and the National Fund for Medical Education, and (2) one-time federal grants, administered locally, for construction and renovation of the physical plant of medical schools. This latter would be similar to the Hill-Burton construction act for hospitals.

The American Medical Association's stand is a strong one if voluntary support is forthcoming. Other groups in society have indicated their willingness to help, but it is up to the medical profession to lead the way in raising funds. Since the time of Hippocrates, we physicians have accepted the obligation to transmit the art of medicine to future generations. We are further obligated by the fact that not one of us paid entirely for our own medical education. If we attended a state school, our training was paid for in part by the taxpayers. If we attended a private university, various philanthropic groups and individuals helped finance our education. The change in tax structure during the past two decades has made it increasingly difficult for individuals to amass great wealth and for states to raise additional funds. Medical education, therefore, must be supported by contributions from a broad base, and the medical profession must constitute its central core.

Full information on the American Medical Education Foundation may be found on advertising page 15. I earnestly ask that every doctor of medicine read this information, consider his obligation to his profession, and give generously to the Foundation. If each physician gives $100 a year, it will provide some 18 million dollars annually for medical education. These gifts would be a direct contribution not only to America's future health but also to the freedom of our profession.

John W. Cline, M.D., San Francisco.

MEDICAL NEWS

ARIZONA

Pathologists and Radiologists Organize.—At a recent meeting the Arizona Association of Pathologists and Radiologists voted to disband in order to allow the organization of separate groups for each specialty. The radiologists reorganized as the Arizona Radiological Society and elected Dr. Maurice R. Richter, Phoenix, president; Dr. Herbert D. Welsh, Tucson, vice president, and Dr. R. Lee Foster, Phoenix, secretary-treasurer. The pathologists organized the Arizona Society of Pathologists with the following officers: Dr. George O. Hartman, Tucson, president; Dr. Onie O. Williams, Phoenix, vice president, and Dr. Ralph H. Fuller, Tucson, secretary-treasurer.

GEORGIA

New Executive Secretary.—The Medical Association of Georgia announces the appointment of Mr. Sid Wrightsman Jr. as executive secretary and public relations director, effective July 15. It is requested that all correspondence be directed to him. The new address of the association is 875 West Peachtree St., N. E., Atlanta. The next annual session of the association will be held in Atlanta, May 11-14, 1952, at the Atlanta Biltmore Hotel.

ILLINOIS

Recommends Restriction of Hospital Visitors.—Restriction of maternity patients' visitors to one a day, preferably the father, has been recommended by the state department of public health in view of reports indicating increased incidence of diarrhea in the general population of the state. In addition to the control of visiting, hospital administrators in cooperation with doctors and nurses are asked to strengthen other control methods so that safe care of mothers and infants may be assured. Physicians are encouraged to report to their local health departments all diarrheal diseases irrespective of cause. There is no known epidemic in hospital nurseries at this time. The objective is to prevent one. The public can help by its understanding, cooperation, and support.

Chicago

Borden Undergraduate Award.—Dr. Robert E. Lee has been named recipient of the Borden Undergraduate Research Award for 1951 at the University of Illinois College of Medicine. The award, representing a gift of $500, for originality and thoroughness of research is presented by the Borden Company Foundation, Inc. Dr. Lee recently received the doctor of medicine degree from the university.

Gift from Solomon Foundation.—The Hektoen Institute for Medical Research of the Cook County Hospital has received a $50,000 check for medical research from the Dr. Jerome D. Solomon Memorial Research Foundation. The foundation is reported to have given a total of $350,000 for work carried on at the institute.

Fellowship Award Renewed.—Dr. Abe Oyamada, a resident in the department of pathology of Mount Sinai Hospital, has been awarded the Ruth Berger Reader Fellowship in the amount of $1,500 for research on hemolytic anemias. This is the second year that this fellowship, supported by the Hematology Foundation in Chicago, has been awarded to Dr. Oyamada, who will carry on his investigations under the supervision of Dr. Israel Davidsohn, professor of pathology at the Chicago Medical School and director of laboratories at Mount Sinai Hospital.

Doctor Grubbe Honored.—Dr. Emil H. Grubbe was guest of honor at a meeting July 11 of the Alumni Association of Hahnemann Medical College, which is no longer in existence. Dr. Grubbe was presented a scroll of honor for his meritorious service in pioneering in radiation therapy. He is credited with being the first scientist ever to use x-rays for healing. Dr. Grubbe was graduated from the college in 1898. His pioneering research cost him his left hand, parts of his upper lip and jaw, and the use of his right hand. Dr. Grubbe retired from active practice two years ago but still sees a few patients in his home.

MAINE

State Secretary Retires.—The council of the Maine Medical Association at its meeting in June released the following statement:

> Dr. Frederick R. Carter of South Portland, who has served as secretary-treasurer of the Maine Medical Association since 1937 has retired from those offices, as well as his positions on the *Journal of the Maine Medical Association*. Dr. Carter . . . has retired for reasons of health. Mrs. Esther M. Kennard, who has served as Dr. Carter's assistant for several years, was elected as acting secretary-treasurer until the council has the opportunity to study carefully such reorganization of these duties as Dr. Carter's retirement makes necessary.

MARYLAND

Personal.—Dr. Alfred Blalock, professor of surgery at Johns Hopkins Medical School, Baltimore, received an honorary doctor of science degree at the University of Rochester, New York, June 12.

New Organization of State Health Department.—Reorganization of the state department of health in accordance with the new health law enacted by the General Assembly of Maryland earlier this year became effective July 1. The recently adopted plan establishes seven bureaus. Only the chiefs of the bureaus and members of the executive office are now directly responsible to the director of health. Chiefs of divisions are accountable to the director through the chiefs of the bureaus to which their programs have been assigned. The changes were recommended on the basis of a survey undertaken in 1949. The seven bureaus are as follows: Office of the Deputy Director, Bureau of Laboratories, Bureau of Preventive Medicine, Bureau of Tuberculosis, Bureau of Medical Services and Hospitals, Bureau of Environmental Hygiene, and Bureau of Management. The executive office consists of a legal adviser, a consultant in public health administration, a public relations assistant, and an administrative assistant.

MASSACHUSETTS

Clearinghouse for Postgraduate Education.—A central clearinghouse of all available information concerning postgraduate medical education in this state is now being set up as a service to physicians by the Massachusetts Medical Society. Instead of having to "shop around" to find a desired program, following completion of a survey now in progress, a physician will need but contact the clearinghouse to be set up in the society's headquarters at 22 The Fenway, Boston. Mrs. Charlotte W. Troutwine of Newton Center is executive secretary. The clearinghouse is sponsored by the society's Committee on Postgraduate Medical Education, in cooperation with the medical schools of Harvard, Boston University, and Tufts; the Lahey Clinic; Massachusetts Heart Association; the Joslin Clinic; Massachusetts Tuberculosis and Health League; National Foundation for Infantile Paralysis, Inc., and the Massachusetts Academy of General Practice.

MINNESOTA

Dr. Lillehei Wins Smith Award.—Dr. C. Walton Lillehei, now associate professor of surgery at the University of Minnesota Medical School, Minneapolis, was recently awarded the Theobald Smith Award in Medical Sciences for 1951. The award, $1,000 and a bronze medal, established by Eli Lilly & Company, Indianapolis, in 1936, was made at a dinner of the Cleve-

---

Physicians are invited to send to this department items of news of general interest, for example, those relating to society activities, new hospitals, education and public health. Programs should be received at least three weeks before the date of meeting.

land meeting of the Federation of American Societies for Experimental Biology. Much of Dr. Lillehei's research has been concerned with endocarditis, glomerulonephritis, and related ailments.

Personals.—The University of Minnesota awarded certificates of merit June 18 to the following veteran members of the Mayo Foundation staff in Rochester: Drs. Donald C. Balfour, Dorr F. Hallenbeck, Melvin S. Henderson, Monte C. Piper, and Harry G. Wood. The certificates were given as "a token of the appreciation which the University feels for their splendid years of service." ——Edward J. Baldes, Ph.D., of the Mayo Foundation, Rochester, has been named "Chevalier de l'Ordre National de la Legion d'Honneur" by the French government, "as a token of gratitude for outstanding services . . . rendered to medical sciences, especially . . . in the field of aeronautics. . . ." The award was presented by M. Francois Briere, consul general of France at Chicago, in Balfour Hall, Mayo Foundation House, July 10.

MISSOURI

County Society Presents Gold Keys.—The Jackson County Medical Society at its installment of officers on June 29 presented gold keys to Dr. Herbert L. Mantz and to Eric Williamson, both of Kansas City. Dr. Mantz has been director of the tuberculosis clinic at the city's General Hospital for 24 years, was president of the Missouri Tuberculosis Association from 1945 to 1948 and of the National Tuberculosis Association in 1949, and now is national consultant in the tuberculosis program of the Veterans Administration. Eric Williamson, an insurance man for 21 years, was cited for his leadership in the Kansas City chapter of the Arthritis and Rheumatism Foundation. He served as the first president of the local chapter of the Arthritis and Rheumatism Foundation and has led its local campaigns and participated in its national program. At the recent convention of the American Rheumatism Association in Atlantic City he was a guest speaker.

NEW MEXICO

State Medical Election.—At the recent annual meeting of the New Mexico Medical Society in Santa Fe, Dr. Leland S. Evans, Las Cruces, was installed as president. Elected officers include Dr. Coy S. Stone, Hobbs, president-elect; Dr. Albert S. Lathrop, Santa Fe, vice president, and Dr. Lucien G. Rice Jr., Albuquerque, secretary-treasurer.

Personal.—Dr. Stuart W. Adler, Albuquerque, has been named "top man of the year" by the local junior chamber of commerce. He has long been active within the medical profession of Bernalillo County and the state and has been a leader in the mass x-ray projects of the tuberculosis association, the health center of the New Mexico Society for Crippled Children, the New Mexico Health Foundation, and the Cerebral Palsy School.

NEW YORK

Award for Discovery of the Coxsackie Virus.—Dr. Gilbert J. Dalldorf, director of the state department of health's Division of Laboratories and Research, has received the Harold J. Fisher Memorial Award for discovery of a virus which produces a disease similar to poliomyelitis. Unlike the virus of poliomyelitis, which attacks the nerves, the virus isolated by Dr. Dalldorf attacks the skeletal muscles, the nervous system being unaffected. He has named the new virus "Coxsackie" because the patients from whom it was first isolated were residents of that village (THE JOURNAL, Feb. 17, p. 488).

New York City

Academy Clarifies Statement on Immunization.—The New York Academy of Medicine through the Committee on Public Health Relations, and with the concurrence of City Commissioner of Health Dr. John F. Mahoney, clarifies the latter's recent advice to physicians in regard to the avoidance of elective injections during the summer months of 1951 (THE JOURNAL, June 30, p. 856).

1. Immunization against smallpox, typhoid fever, and other communicable diseases should be given to all persons who are about to leave the country, as required by law or the regulations of the immigration authorities.

2. Immunization against smallpox, typhoid fever, rabies, diphtheria, and other communicable diseases should be given during an epidemic or local endemic of these diseases to all susceptible persons who may be exposed to the infection.

3. Immunization against smallpox and typhoid fever should be given to children who are to travel or vacation in areas where they may be exposed to such infection.

4. Desensitization against hay fever, asthma, and other allergic conditions is warranted.

5. Insulin therapy should be continued in diabetic children and adults.

6. Penicillin and other antibiotics as well as other life-saving injections should be administered during summer months whenever indicated clinically.

7. Primary immunization of the population against diphtheria, tetanus, and whooping cough should be concentrated in the first six months of life. Repetition of such immunization at a later age should be carried out November 1 to April 30 during the year 1951-52, but this general rule should not prevent a physician from giving such immunizations during the summer months to persons exposed to infection if in his judgment there is danger of acquiring such infection.

OREGON

Dr. Hill to Head Pediatric Department.—Dr. Allan J. Hill Jr., clinical assistant professor of pediatrics at the University of Minnesota Medical School, Minneapolis, has been appointed head of the department of pediatrics at the University of Oregon Medical School, Portland, and chief of the Doernbecher Memorial Hospital for Children.

SOUTH CAROLINA

State Medical Election.—Among the officers of the South Carolina Medical Association chosen at its recent annual meeting are Dr. Joseph D. Guess, Greenville, who was installed as president, and Dr. Lawrence P. Thackston, Orangeburg, president-elect. The secretary is Dr. Nathaniel B. Heyward, Columbia, and the treasurer Dr. J. Howard Stokes, Florence.

WEST VIRGINIA

School Health Conference.—The third Annual Working Conference on School Health will be held at Jackson's Mill during the week of August 20. The conference is sponsored by the state departments of health and of education and West Virginia University. The program will be broken down into general school health instruction, nutrition instruction, and safety instruction. The conference will be strictly a working conference in which those who attend will have an opportunity to participate and present their problems for group assistance. Expert consultants on school health will be present in an advisory capacity.

GENERAL

Conference on Alcoholism.—The National States' Conference on Alcoholism will hold its annual meeting at the Hotel Taft in New Haven, Conn., August 5-8. The program includes reports on state activities and developments in related agencies, including the World Health Organization, National Committee on Alcoholism, American Psychiatric Association, U. S. Public Health Service, and the Committee on Chronic Illness of the American Medical Association. There will be reports on research developments and discussions of problems of therapy. Details may be obtained from the program chairman, Walter O. Cromwell, 310 North Orchard St., Madison 2, Wis.

French Stamp Honors Medical Military Medicine.—A 15-franc stamp issued by France on June 18 honors military medicine. It pictures the Val-de-Grace Chapel, a religious edifice which in 1793 was transformed into a military instruction hospital, and in 1850 into a school of military health service. It also carries the portraits of three medical scientists identified with the service: Robert Picque (1877-1927), a surgeon who pioneered in performing operations at the front in World War I; Zacharie Roussin (1827-1894), pharmacist and toxicologist, and Antoine Villemin (1827-1892), a physician who did tuberculosis research.

WHO Regional Office in Manila.—The World Health Organization Regional Office for the Western Pacific was formally established May 21, as the regional committee held its first session in Geneva with the participation of 12 countries and of states having trust territories in that region. The committee recommended the selection of Manila as the permanent headquarters for the regional office. It also nominated Dr. I. C. Fang, present director of the temporary regional office in Hong Kong, as permanent regional director. Both decisions were confirmed by the WHO executive board in Geneva in June. The first session of the regional committee, which elected Dr. R. G. Padua, vice health minister of the Philippines, as chairman, was attended by representatives of Australia, New Zealand, Viet Nam, Cambodia, Philippines, Laos, Korea, Japan, France, United Kingdom, Netherlands, and Portugal. The representative from Australia was present as an observer.

Action on Shortage of Insecticides.—As one of a series of steps designed to relieve a world shortage of chlorine-based insecticides, including DDT, the World Health Organization has asked the United Nations to set up a special body to investigate the problem. A communication from Dr. Brock Chisholm, WHO director-general, will be placed before the 13th session of the Economic and Social Council opening on July 30 in Geneva. WHO points out that the availability of insecticides has been sharply affected by the shortage of essential raw materials (chlorine, benzene, and sulphuric acid) resulting from defense programs of the major producing countries. A survey of public health requirements of insecticides for all member states showed that a total of 23,688,000 pounds of DDT will be needed for the last half of 1951 and the full year of 1952.

Personals.—Dr. Donald D. Van Slyke of the Brookhaven National Laboratory, Upton, N. Y., has become a counselor of the Lilly Research Grants sponsored by Eli Lilly & Company, Indianapolis. Since 1948 he has been assistant director and physiologist at the Brookhaven National Laboratory, assisting in the organization of the departments of biology and medicine, and during the past two years he has also served as chemist in the department of medicine. Although now relinquishing his administrative responsibilities as assistant director at the Brookhaven Laboratory, Dr. Van Slyke will continue his research work there in the department of medicine.——At the annual session of the American College of Physicians Dr. Rolla E. Dyer, director of research, Emory University, was awarded the James D. Bruce Memorial Medal for 1951 in the field of preventive medicine.

Fund for Fundamental Research.—Sharp & Dohme, Inc., Glenholden, Pa., has authorized $50,000 to be placed in a special fund for grants to outstanding university scientists for the advancement of fundamental research in the fields of biology, microbiology, and chemistry. At the same time two grants of $10,000 each were made from this new fund to Wilbur W. Swingle, Ph.D., department of biology, Princeton University, Princeton, N. J., and to Dr. Stanley J. Sarnoff, School of Public Health, Harvard University, Boston. The grants are to be awarded on a year-to-year basis, but grants may be renewed for at least two additional years. There will be complete freedom of communication and publication of the results of the research supported by the grants. Dr. Swingle will conduct basic investigations on the adrenal cortex and resistance to toxic agents. Dr. Sarnoff will direct basic research in the cardiovascular field with special emphasis on the causes and prevention of lung edema.

Home Care Plans for Poliomyelitis.—A March of Dimes grant of $18,262 will enable the American Physical Therapy Association to include a continuing study of home care plans for polio and other patients in its educational program. Since 1946 a broad educational program has been undertaken by the association with the assistance of the National Foundation for Infantile Paralysis to recruit more students for physical therapy training, to make more effective the professional training, to provide visual aids and instructional material to meet the needs of graduate physical therapists in providing better care for poliomyelitis patients, and to improve personnel practices in the field. The grant will enable the association to continue its extensive study of the various physical therapy home care plans now in operation throughout the country. Association officials point out that it is becoming impossible to care for large numbers of polio patients in institutions for long periods of time because of the lack of hospital beds, insufficient professional personnel, and the high cost of institution care. Completion of the study on home care plans will enable the association to provide guidance to the agencies providing physical therapists for home care as well as advising the physical therapists thus employed. Efforts will also be made to have physical therapy home care plans included in school curricula and to stimulate physical therapists to accept field service employment.

Prevalence of Poliomyelitis.—According to the National Office of Vital Statistics, the following number of reported cases of poliomyelitis occurred in the United States in the weeks ending as indicated:

Division and State	July 14, 1951	July 7, 1951

FOREIGN

Congress on Rheumatology.—The Second European Congress of Rheumatology of the Ligue Européenne Contre le Rhumatisme, organized by the Spanish Society of Rheumatism, will be held in Barcelona, Spain, September 24-27. Congress papers will discuss non articular rheumatism, effects of pituitary and adrenal cortex hormones in rheumatic diseases, untrasonic therapy, ankylosing spondilitis, and brucellar rheumatism. The Spanish society is interested in the organization of a bibliographic exhibition of monographs and books edited during the last 20 years. Those who have edited such publications are invited to send a copy of each to (S.) Pedro Barcelo, General Secretary, Barcelona, Spain.

EXAMINATIONS AND LICENSURE

NATIONAL BOARD OF MEDICAL EXAMINERS

National Board of Medical Examiners: *Parts I and II.* Various Centers. Sept. 5-7 (Part I only). Applications must be filed at least thirty days prior to an examination. Ex. Sec., Mr. E. S. Elwood, 225 S. 15th St., Philadelphia.

INTERNATIONAL COLLEGE OF SURGEONS

Examinations for Certified Fellowship in the United States Chapter in General and Orthopedic Surgery, Chicago, Aug. 3-4. Sec., Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago 10.

EXAMINING BOARDS IN SPECIALTIES

American Board of Anesthesiology: *Oral.* Memphis, Oct. 14-17. Sec., Dr. Curtiss B. Hickcox, 80 Seymour St., Hartford 15, Conn.

American Board of Dermatology and Syphilology: *Written.* Chicago, March 1952. *Oral.* Chicago, May 1952. Final date for filing application is Feb. 1, 1952. Sec., Dr. George M. Lewis, 66 E. 66th St., New York 21.

American Board of Internal Medicine: *Written.* Various centers, Oct. 15. Final date for filing applications was May 1. *Oral.* The schedule of oral examinations for 1951 has been arranged on a regional basis as follows: New York, date to be announced, covering Maine, Massachusetts, New Hampshire, New York and Vermont. San Francisco, date to be announced, covering Arizona, California, Colorado, Idaho, Montana, New Mexico, Oregon, Utah and Washington.

Only candidates who have not taken an oral examination can be admitted under the schedule arranged thus far.

Closing dates for the filing of applications for examinations in New York and San Francisco to be announced.

Oral examinations in the subspecialties will be held at the same time and place and on the same distribution.

Exec. Sec., Dr. William A. Werrell, 1 W. Main St., Madison 3.

American Board of Neurological Surgery: *Oral.* Chicago, Oct. 25-26. *Oral.* Chicago, May 1952. Final date for filing applications for the May 1952 examination is Jan. 1, 1952. Sec., Dr. W. J. German, 789 Howard Ave., New Haven 4, Conn.

American Board of Obstetrics and Gynecology: *Written.* Feb. 1, 1952. Final date for filing applications is Nov. 1. *Oral.* Chicago, June 7-13, 1952. Final date for filing application is Feb. 1, 1952. Sec., Dr. Paul Titus, 1015 Highland Building, Pittsburgh 6, Pa.

American Board of Ophthalmology: *Written.* Twenty-five centers, Feb. 4-5, 1952. *Oral.* Chicago, October 8-13. Sec., Dr. Edwin B. Dunphy, 56 Ivie Road, Cape Cottage, Maine.

American Board of Orthopaedic Surgery: Final date for filing applications for the 1952 Part II examinations is Aug. 15, 1951. Sec., Dr. Harold A. Sofield, 122 S. Michigan Ave., Chicago 3.

American Board of Otolaryngology: *Oral.* Chicago, Oct. 8-12. Sec., Dr. Dean M. Lierle, University Hospital, Iowa City.

American Board of Pediatrics: *Oral.* Buffalo, Oct. 26-28. Ex. Sec., Dr. John McK. Mitchell, 6 Cushman Rd., Rosemont, Pa.

American Board of Plastic Surgery: Denver, Oct. 27-29. Final date for filing of case reports is Aug. 30. Sec., Dr. Bradford Cannon, Office of the Board: 4647 Pershing Ave., St. Louis 8.

American Board of Preventive Medicine: *Written.* San Francisco, October 28. *Oral.* San Francisco, October 29. Sec., Dr. Ernest L. Stebbins, 615 North Wolfe St., Baltimore 5.

American Board of Proctology: Philadelphia, Nov. 17-18. Sec.-Gen., Dr. Louis A. Buie, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Psychiatry and Neurology: *Oral.* New York, Dec. 17-18. Final date for filing applications is Sept. 1. Act. Sec., Dr. David A. Boyd Jr., 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Radiology: *Oral.* Washington, D. C., Sept. 17-22. Sec., Dr. B. R. Kirklin, 102-110 Second Ave., S.W., Rochester, Minn.

American Board of Surgery: *Written.* Various centers, Oct. 1951. Final date for filing applications is July 1. *Written.* Various Centers. March 1952. Final date for filing application is Dec. 1, 1951. Sec., Dr. J. Stewart Rodman, 225 S. 15th St., Philadelphia.

Board of Throacic Surgery: *Written.* Various parts of the country. Sept. 14, 1951. Final date for filing applications is July 15. Sec., Dr. William M. Tuttle, 1151 Taylor Ave., Detroit 2, Mich.

American Board of Urology: Chicago, Feb. 9-13, 1952. Final date for filing applications is Sept. 1. Sec., Dr. Harry Culver, 30 Westwood Rd., Minneapolis 16.

MEETINGS

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, The Homestead, Hot Springs, Va., Sept. 6-8. Dr. William F. Mengert, 2211 Oak Lawn Ave., Dallas, Texas, Secretary.

American Congress of Physical Medicine, Shirley-Savoy Hotel, Denver, Sept. 4-8. Dr. Walter J. Zeiter, 2020 E. 93d St., Cleveland 6, Executive Director.

American Hospital Association, St. Louis, Sept. 17-20. Mr. George Bugbee, 18 E. Division St., Chicago 10, Executive Director.

Colorado State Medical Society, Denver, Sept. 18-21. Mr. Harvey T. Sethman, 1612 Tremont Place, Denver 2, Executive Secretary.

Mississippi Valley Medical Society, Peoria, Ill., Sept. 19-21. Dr. Harold Swanberg, 510 Maine St., Quincy, Ill., Secretary.

Montana Medical Association, Great Falls, Sept. 13-16. Mr. L. R. Hegland, 104 N. Broadway, Billings, Executive Secretary.

National Medical Association, Philadelphia, Aug. 20-24. Dr. John T. Givens, 1108 Church St., Norfolk 10, Va., General Secretary.

Nevada State Medical Association, Riverside Hotel, Reno, Sept. 13-15. Dr. Wesley W. Hall, 307 W. Sixth St., Reno, Secretary.

North Texas-Southern Oklahoma Fall Clinical Conference, Wichita Falls, Texas, Sept. 19. Dr. W. L. Powers, 517 Hamilton Bldg., Wichita Falls, Chairman.

Pennsylvania, Medical Society of the State of, Pittsburgh, Sept. 16-20. Dr. Walter F. Donaldson, 500 Penn Ave., Pittsburgh 22, Secretary.

Reno Surgical Society Conference, Riverside Hotel, Reno, Nev., Aug. 23-25. Dr. Olin C. Moulton, 130 N. Virginia St., Reno, Nev., Chairman.

Rocky Mountain Radiological Society, Denver, Aug. 9-11. Dr. Maurice D. Frazer, 1037 Stuart Building, Lincoln, Nebr., Secretary.

U. S. Chapter, International College of Surgeons, Palmer House, Chicago, Sept. 10-14. Dr. Arnold S. Jackson, 1516 Lake Shore Drive, Chicago, Executive Secretary.

Utah State Medical Association, Salt Lake City, Sept. 13-15. Dr. T. C. Weggeland, 42 S. Fifth East St., Salt Lake City, Secretary.

Washington State Medical Association, Seattle, Sept. 9-12. Dr. James W. Haviland, 338 White-Henry-Stuart Bldg., Seattle, Secretary.

INTERNATIONAL

European Congress on Rheumatism, Barcelona, Spain, Sept. 24-27. Dr. Gunnar Edstròn, Sweden, Secretary.

General Practitioners Study Club International, Rome, Italy, Sept. 12-15. Dr. John O'Connell, 10300 Lackland Road, St. Louis 14, Mo., U. S. A., President.

International Anesthesia Research Society, London, England, Sept. 3-7. Mr. R. W. Cope, University College Hospital, London W.C.1, England.

International Association of Allergists, Zurich, Switzerland, Sept. 23-29. Prof. A. S. Grumbach, Hygiene Institut der Universitaet Zurich, Gloriastr. 32, Zurich, Switzerland.

International Congress of Anesthesiology, Nursing School of the Salpiettre, 47 Boul de l'Hospital, Paris, France, Sept. 20-22. 12 rue de Seine, Paris 6^e, France, Secretariat.

International Congress on Entomology, Amsterdam, Holland, Aug. 17-24. Dr. J. de Wilde, 136 Rapenburgerstraat, Amsterdam, Secretary.

International Congress on Industrial Medicine, Instituto Superior Técnico, Lisbon, Portugal, Sept. 9-15. Dr. Luis Guerreiro, Instituto Nacional do Trabalho e Previdência, Praça do Comercio, Lisbon, Secretary General.

International Congress on Mental Health, Mexico City, Mexico, Dec. 11-19. Mrs. Grace E. O'Neill, Division of World Affairs, National Association on Mental Health, 1790 Broadway, New York 19, N. Y.

International Congress of Physical Medicine, London, England, July 14-19. Dr. A. C. Boyle, 45, Lincoln's Inn Fields, London, W.C.2, England, Honorary Secretary.

International Gerontological Congress, Hotel Jefferson, St. Louis, Mo., U. S. A., Sept. 9-14. Dr. John E. Kirk, 5600 Arsenal Street, St. Louis 9, Mo., Chairman, Program Committee.

International Poliomyelitis Congress, Copenhagen, Denmark, Sept. 3-7. Prof. Dr. Niels Bohr, Statens Seruminstitut, 80 Amager Blvd., Copenhagen S., Denmark, President.

International Society of Surgery, Paris, France, Sept. 24-29. Dr. L. Dejardin, 141, rue Belliard, Brussels, Belgium, Secretary General.

International Society for the Welfare of Cripples, Fifth World Congress, Stockholm, Sweden, Sept. 9-14. Mr. Donald V. Wilson, 54 E. 64th St., New York 21, N. Y., U. S. A., Executive Director.

Pan Pacific Surgical Association Congress, Honolulu, Hawaii, Nov. 7-19. Dr. Forrest J. Pinkerton, Suite 7, Young Bldg., Honolulu, Hawaii, President.

World Confederation for Physical Therapy, Copenhagen, Denmark, Sept. 7-8.

World Medical Association, Stockholm, Sweden, Sept. 15-21. Dr. Louis H. Bauer, 2 E. 103d St., New York 29, N. Y., U. S. A., Secretary General.

DEATHS

Copps, Lyman Alden ⊕ Marshfield, Wis.; born in Stevens Point, Wis.; May 14, 1889; Rush Medical College, Chicago, 1915; specialist certified by the American Board of Ophthalmology and the American Board of Otolaryngology; member of the American Academy of Ophthalmology and Otolaryngology; fellow of the American College of Surgeons; a founder of the Wisconsin and Upper Michigan Society of Ophthalmology; a member of the state medical advisory committee to the state board of vocational and adult education since 1949; served during World War I; president of the Marshfield Chamber of Commerce; a preceptor of the University of Wisconsin Medical School in Madison; at one time on the faculty of the University of Illinois College of Medicine in Chicago; president of the Marshfield Clinic since 1942; affiliated with St. Joseph's Hospital, where he was at one time chief of staff; recently appointed to the state board of health by the governor; died April 2, aged 61, of cerebral vascular occlusion.

Fuller, Earl William ⊕ Greystone Park, N. J.; born in Utica, N. Y., July 3, 1885; Albany (N. Y.) Medical College, 1908; an Associate Fellow of the American Medical Association; member of the Medical Society of the State of New York, American Psychiatric Association, Association for Research in Nervous and Mental Diseases, and the American Orthopsychiatric Association; fellow of the National Committee on Mental Health; specialist certified by the American Board of Psychiatry and Neurology; director of the Northern New Jersey Mental Hygiene Clinics, New Jersey State Hospital; consulting psychiatrist, outpatient department, Englewood (N. J.) Hospital; consulting psychiatrist, Children's Heart Unit, Victoria Foundation, Morris Plains; consultant, Mental Hygiene Commission, New Jersey State Department of Institutions and Agencies in Trenton; at one time superintendent of the Pennhurst (Pa.) State School; died May 16, aged 65, of coronary thrombosis.

Weinberger, Herbert Leon ⊕ New Orleans; born in Laurel, Miss., Oct. 25, 1901; Tulane University of Louisiana School of Medicine, New Orleans, 1926; formerly on the teaching staff of the Tulane Post Graduate School of Medicine, and later on the staff of Louisiana State University School of Medicine; specialist certified by the American Board of Internal Medicine; served on the staff of Touro Infirmary as senior in the department of gastroenterology, and later as chief of the service; formerly vice president of the Louisiana Society of Gastroenterology; member of the American Society of Tropical Medicine and the National Gastroenterological Association, serving as president of its New Orleans chapter; died in Touro Infirmary May 4, aged 49, of coronary thrombosis.

Jack, Frederick Lafayette, Boston; born in Boston in 1861; Harvard Medical School, Boston, 1884; specialist certified by the American Board of Otolaryngology; member of the American Medical Association and the American Laryngological, Rhinological and Otological Society, of which he had been vice president; first president of the New England Oto-Laryngological Society; past president and secretary of the American Otological Society; fellow of the American College of Surgeons; served on the staffs of the Massachusetts Eye and Ear Infirmary and Massachusetts General Hospital; died May 3, aged 90, of cerebral thrombosis.

Schreiner, Bernard Francis ⊕ Buffalo; University of Buffalo School of Medicine, 1909; an Associate Fellow of the American Medical Association; fellow of the American College of Surgeons; specialist certified by the American Board of Radiology; member of the Radiological Society of North America, American College of Radiology and the American Radium Society, of which he had been vice president; formerly instructor in surgery at his alma mater; served on the staffs of the Buffalo General Hospital, Roswell Park Memorial Institute, and Sisters of Charity Hospital; died May 8, aged 64, of coronary thrombosis.

Ausman, Carl Frederick, St. Paul; Northwestern University Medical School, Chicago, 1912; member of the American Medical Association; on the staffs of Mounds Park Hospital, Riverview Hospital, and St. Luke's Hospital, where he died May 23, aged 67, of hypostatic pneumonia and cerebrovascular accident.

Beyer, Hart ⊕ Pittsville, Wis.; Rush Medical College, Chicago, 1900; served as village health officer, for many years as city clerk, and as a member of the board of education; died April 15, aged 78, of coronary thrombosis.

Bierly, Fred, Elizabeth, Ind.; Kentucky School of Medicine, Louisville, 1908; served on the staff of St. Edward Hospital in New Albany; died May 11, aged 69, of coronary occlusion.

Bishop, John S., Portland, Ore.; Boston University School of Medicine, 1886; died March 24, aged 91.

Bowen, Charles Fred, Richland Center, Wis.; Milwaukee Medical College, 1897; died April 2, aged 82.

Bowen, William Sinclair, Washington, D. C.; University of Maryland School of Medicine, Baltimore, 1888; member of the American Medical Association; fellow of the American College of Surgeons; formerly clinical professor of obstetrics at the George Washington University School of Medicine; consulting obstetrician, Columbia Hospital for Women; died May 18, aged 84, of coronary thrombosis and arteriosclerosis.

Brennglass, Joachim ⊕ New York; Columbia University College of Physicians and Surgeons, New York, 1903; an Associate Fellow of the American Medical Association; died March 28, aged 80.

Briggs, Stanley J., Madison, Wis.; Rush Medical College, Chicago, 1901; member of the American Medical Association; died in Madison General Hospital March 15, aged 73, of carcinoma of the sigmoid.

Brinkman, George Franklin, Fort Lauderdale, Fla.; Ohio Medical University, Columbus, 1900; died April 11, aged 72, of arteriosclerosis.

Buttorff, Gordon Stephen ⊕ Louisville, Ky.; Indiana University School of Medicine, Indianapolis, 1923; assistant professor of medicine at the University of Louisville School of Medicine; member of the American Rheumatism Association and the Aero Medical Association; on the staffs of the St. Joseph Hospital, Kentucky Baptist Hospital, Kosair Crippled Children's Hospital, and St. Anthony's Hospital, where he died May 16, aged 52, of cerebral hemorrhage.

Carr, Percy Whitman, Boston; Harvard Medical School, Boston, 1905; died March 31, aged 69.

Conner, Homer Leigh ⊕ Lieutenant Colonel, U. S. Army, Santa Monica, Calif.; Harvard Medical School, Boston, 1900; served during World War I; entered the medical corps of the U. S. Army as a major in July 1920; retired June 30, 1937, with rank of lieutenant colonel, for disability in line of duty; died March 27, aged 74, of cerebral thrombosis and coronary thrombosis.

Daley, Lyle Miner, Hamilton, Mo.; St. Louis University School of Medicine, 1908; member of the American Medical Association; served during World Wars I and II; died in Polo, April 13, aged 66, of coronary occlusion.

Eddleman, Owen Albert, Benton, Ky.; Chattanooga (Tenn.) Medical College, 1902; member of the American Medical Association; served during World War I; died in the Riverside Hospital, Paducah, March 8, aged 74.

Hesser, John Jacob ⊕ Chicago; Magyar Kiralyi Pázmány Petrus Tudományegyetem Orvosi Fakultasa, Budapest, Hungary, 1909; clinical associate in the department of medicine, Rush Medical College from 1924 to 1934; member of the Illinois Selective Service System during World War II; on the staff of Edgewater and Manor hospitals; died March 30, aged 64, of acute myocardial infarction and adhesive pericarditis.

⊕ Indicates Fellow of the American Medical Association.

Howell, Katharine Myrta ⊕ Chicago; Rush Medical College, Chicago, 1913; specialist certified by the American Board of Pathology; member of the American Association of Pathologists and Bacteriologists, College of American Pathologists, Society of American Bacteriologists, and the American Society of Clinical Pathologists; on the staff of Michael Reese Hospital; died April 27, aged 67.

Humphrey, Thomas Field, Dayton, Ohio; University of Cincinnati College of Medicine, 1931; specialist certified by the American Board of Pediatrics; member of the American Academy of Pediatrics; affiliated with Good Samaritan and Miami Valley hospitals; died May 11, aged 52, of coronary thrombosis.

Hyde, William George, Milwaukee; Rush Medical College, Chicago, 1913; assistant medical director of Northwestern Mutual Life Insurance Company; died in Madison March 27, aged 65, of coronary thrombosis.

Jackson, Calvin Franklin ⊕ Bradshaw, W. Va.; Ohio State University College of Medicine, Columbus, 1927; member of the Maine Medical Association; served during World War I; died suddenly May 12, aged 52, of coronary thrombosis.

Jensen, Ingvald Johan, Chicago; University of Illinois College of Medicine, Chicago, 1922; member of the American Medical Association; died May 16, aged 58, of carcinoma of the prostate.

Lee, Richard Nicholas, Mount Blanchard, Ohio; Starling Medical College, Columbus, 1898; member of the American Medical Association; served on the school board and town council; affiliated with Findlay Hospital in Findlay; died May 17, aged 78, of coronary thrombosis.

Lochhead, John McLean, Indianapolis; Homeopathic Medical College of Missouri, St. Louis, 1894; died in Methodist Hospital May 15, aged 83, of hypostatic pneumonia.

Loescher, Walter Otto, St. Louis; American Medical College, St. Louis, 1914; died May 16, aged 61.

Lyons, George Canfield ⊕ Larchmont, N. Y.; University and Bellevue Hospital Medical College, New York, 1905; veteran of the Spanish-American War and World War I; for many years police surgeon; affiliated with New Rochelle (N. Y.) Hospital; died May 9, aged 71, of carcinoma of the bronchus.

McClelland, Joseph O., Maxton, N. C.; Medical College of Virginia, Richmond, 1908; member of the American Medical Association; past president of Robeson County Medical Society; past president and vice president of the Seaboard Airline Railway Surgeons; for many years surgeon for the Seaboard Airline Railway; affiliated with Baker Sanatorium and Thompson Hospital in Lumberton; died in a hospital at Lumberton May 8, aged 78, of cerebral embolism and Parkinson's disease.

Martin, George A. E., Adona, Ark. (licensed in Arkansas in 1903); died May 15, aged 94, of heart disease.

Martin, Leonard James, Asbury Park, N. J.; Howard University College of Medicine, Washington, D. C., 1935; member of the American Medical Association; served in the South Pacific during World War II; affiliated with Monmouth Memorial Hospital in Long Branch and Fitkin Memorial Hospital in Neptune; died May 15, aged 46, of a tumor of the lung.

Moberley, Paul Benton, Fort Smith, Ark.; University of Illinois College of Medicine, Chicago, 1941; member of the American Medical Association; served during World War II; affiliated with Veterans Administration Hospital (Kennedy), where he died May 12, aged 41, of periarteritis nodosa.

Murry, Abel Vance, Macon, Miss.; Tulane University of Louisiana School of Medicine, New Orleans, 1932; member of the American Medical Association; served during World War II; died in Lonoke, Ark., May 18, aged 44, of heart disease.

Nunemaker, Tunis ⊕ Portsmouth, Ohio; College of Physicians and Surgeons, Baltimore, 1901; on the staff of Mercy Hospital, where he died May 16, aged 78, of carcinoma of the stomach and cerebral hemorrhage.

Patrick, Fred Edward Jr., Kansas City, Mo.; University of Kansas School of Medicine, Kansas City, Kan., 1943; served during World War II; died May 16, aged 32, of cerebral hemorrhage.

Richmond, Henry Charles Tyler, Louisville, Ky.; Hospital College of Medicine, Louisville, 1907; member of the American Medical Association; fellow of the American College of Surgeons; served in France during World War I; affiliated with Jewish Hospital, where he died May 9, aged 66, of heart disease.

Rogers, Herbert Wilson ⊕ Norfolk, Va.; born in Nassawadox, Va., Aug. 26, 1892; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1916; member of the Southeastern Surgical Congress; past president of the Norfolk County Medical Society; for many years member of the school board of Norfolk; member of the board of directors of the Virginia Academy of General Practice; affiliated with Leigh Memorial Hospital and Norfolk General Hospital, where he died May 8, aged 58, of uremia.

Roth, Harry A. ⊕ Long Beach, Calif.; McGill University Faculty of Medicine, Montreal, Canada, 1930; affiliated with St. Mary's Long Beach Hospital and Seaside Hospital, where he died May 12, aged 43, of coronary thrombosis.

Roth, Lionel Andre, Midland, N. C.; College of Medical Evangelists, Loma Linda-Los Angeles, 1945; interned at Washington Sanitarium and Hospital in Washington, D. C.; died May 16, aged 31, of injuries received in an automobile accident.

Schierge, Ernest E., Plainfield, N. J.; Bellevue Hospital Medical College, New York, 1890; formerly affiliated with Municipal Sanatorium of the Department of Health, New York City, in Otisville; died in Muhlenberg Hospital May 15, aged 83, of cerebral thrombosis.

Shoemaker, John Asher, Gallipolis, Ohio; University of Pennsylvania Department of Medicine, Philadelphia, 1902; contract surgeon for the U. S. Army during World War I; at one time practiced in Berea, where he was co-founder and for many years a member of the staff of Community Hospital; served on the staff of the Gallipolis State Institute; died May 2, aged 70, of coronary disease.

Spottswood, Edward W., Missoula, Mont.; University of Minnesota College of Medicine and Surgery, Minneapolis, 1893; member of the House of Delegates of the American Medical Association in 1920 and 1921; for many years affiliated with the Northern Pacific Hospital; died May 13, aged 85.

Swanson, Robert Ralph, Minneapolis; University of Minnesota Medical School, Minneapolis, 1927; member of the American Medical Association; died May 14, aged 49.

Temple, Henry Curtis, Alliance, Ohio; St. Louis College of Physicians and Surgeons, 1888; on the staff of Alliance City Hospital; died May 8, aged 93, of congestive heart failure.

Warren, John Freemont ⊕ Ithaca, N. Y.; University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore, 1920; past president of the Tompkins County Medical Society; affiliated with Ithaca Hospital; died May 13, aged 55, of coronary thrombosis.

Werner, Emil August, Panama City, Fla.; Baylor University College of Medicine, Dallas, Texas, 1917; served during World War II; formerly affiliated with the Veterans Administration; died in Pensacola, Fla., May 6, aged 60, of carcinoma of the kidneys.

Wheat, Thomas Adrian, Lewisburg, Tenn.; University of Tennessee College of Medicine, Memphis, 1938; member of the American Medical Association; medical superintendent of Wheat Memorial Hospital; died May 9, aged 36, of virus encephalitis.

Whelan, Raymond Edward, Youngstown, Ohio; Western Reserve University Medical Department, Cleveland, 1890; also a graduate in pharmacy; fellow of the American College of Surgeons; veteran of the Spanish-American War; at one time personal physician to the late President Taft; past president of the Mahoning County Medical Society; one of the founders and for many years emeritus chief of staff of St. Elizabeth's Hospital, where he died May 6, aged 82, of diverticulitis of the esophagus and bronchopneumonia.

Wright, Elihu Burritt, Pierce City, Mo.; Barnes Medical College, St. Louis, 1898; served as mayor of Pierce City and as president of the school board; died in St. John's Hospital, Springfield, May 8, aged 89.

GOVERNMENT SERVICES

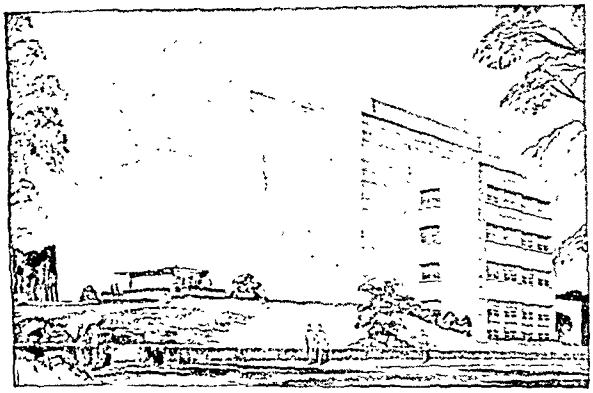
ARMY

New Institute of Pathology.—Ground breaking ceremonies for the new Armed Forces Institute of Pathology took place July 10, at the Army Medical Center, Washington, D. C.

Among those who participated were Brig. Gen. Elbert DeCoursey, Director of the Institute; Rear Admiral H. L. Pugh, Surgeon General of the Navy; Maj. Gen. H. G. Armstrong, Surgeon General of the Air Force; Vice Admiral Joel T. Boone, MC, USN, (ret.), Chief Medical Director of the Veterans Administration; and Dr. Leonard Scheele, Surgeon General, U. S. Public Health Service. Surgeon General Armstrong of the Army was the principal speaker.

The $7,250,000 structure will take about two years to build. The exterior walls will be of concrete 12 inches thick, and three of its eight floors will be underground. Except for the part which will house offices, the building will be entirely without windows and will be equipped with special high intensity, controlled lighting. Also included are plans for central closed circuit television facilities which are to be used in teaching both Army and civilian students.

The air-conditioned building will provide about 200,000 square feet of working space.



Architect's conception of the new Institute of Pathology.

During the past half century, five different attempts have been made to obtain funds necessary to construct new quarters for the Armed Forces Institute of Pathology, which before unification of the military establishment had been known as the Army Medical Museum and the Army Institute of Pathology. Now located at 7th and Independence Avenue, Washington, D. C., the Institute occupies a structure built in 1887. Constantly increasing demands for the services offered by the Institute have made it imperative that adequate, modern housing be obtained if those services were to be maintained at the necessary high standards.

Under the Army Surgeon General's Office, the Armed Forces Institute of Pathology is made up of four departments. The Laboratories of Pathology furnish consultation and diagnosis services on specimens submitted by military and other federal hospitals, medical schools, and civilian hospitals and medical institutions all over the world. The American Registry of Pathology, operating under the auspices of the National Research Council, conducts investigations in specific fields of pathology. All of its materials and records are available to medical officers, graduate and other qualified students, and other professional investigators. The Medical Illustration Service prepares medical exhibits and material for use in training. The Medical Museum collects and preserves gross material, instruments, and other items of historic medical significance.

Dr. Edsall to Aid Army Graduate School.—Dr. Geoffrey Edsall, head of the department of microbiology, Boston University School of Medicine, has been granted a one-year leave of absence to serve as head of the Immunological Division, and director of the Division of Biologic Products, at the Army Medical Graduate School, Washington, D. C. Dr. Edsall has been a pioneer in vaccine and serum development, and in the organization of large-scale civilian blood programs and the utilization of blood fractions in the arresting of disease. Since joining the medical faculty of the university in July, 1949, he has been doing research on simplified methods of immunizing adults against diphtheria and tetanus. Previously, he was director of the Division of Biological Laboratories, Massachusetts Department of Public Health.

Personal.—Maj. Richard H. Baker, MC, has been assigned as professor of military science and tactics in charge of the Medical Reserve Officers Training Corps at the St. Louis University School of Medicine. Maj. Baker was orthopedic surgeon in a mobile army surgical hospital unit in Korea from July to December 1950, when he returned to Fitzsimons General Hospital, Denver, to complete his orthopedic residency training begun in 1949 shortly after joining the regular army.

PUBLIC HEALTH SERVICE

Malaria Approaching Extinction in United States.—More than 98% of the American houses sprayed with DDT (dichloro-diphenyl-trichloro-ethane) between 1945 and 1950 have been kept free of malaria mosquitoes, according to the Communicable Disease Center of the Public Health Service. State health departments and CDC applied more than 6,220,000 doses of the insecticide during that six-year period, according to a report by Dr. George H. Bradley, chief of entomologic services, and Christ A. Hansen, chief of engineering services, both of the Communicable Disease Center.

"It is significant that the percentage of control obtained in 1950 compares favorably with that for previous years," they said. "Thus we may conclude that resistance to DDT has not yet become a problem in our antianopheline mosquito control program." The extensive use of DDT residual, or long-lasting, spraying for malaria control in the United States was begun in 1945. About 700,000 house spray applications were made during that year; 1,100,000 in 1946; 1,278,000 in 1947; 1,300,000 in 1948; 1,000,000 in 1949; and 842,000 in 1950. "Malaria appears to be approaching extinction in the United States," Dr. Bradley and Mr. Hansen concluded. "Only 2,214 cases were reported for 1950, as compared to 62,763 cases reported in 1945."

Even so, the reported cases give an exaggerated picture of malaria incidence, they concluded. During the past year epidemiologists of the Communicable Disease Center have made a concerted effort to evaluate all reported cases of malaria to determine their validity. Of 676 supposed cases appraised in seven southeastern states, only 26 were proved to be parasite-positive. Of these 26 positive cases, only 6 were considered to have been transmitted within the United States.

AIR FORCE

Dr. Boothby Goes to New Mexico.—Dr. Walter M. Boothby, for the past eight months advisor for research at the Air Force Medical School, Randolph Field, Texas, has left the school to take over a new post at the Lovelace Foundation in Albuquerque, N. M. (The Journal, Dec. 16, 1950, p. 1382). At the Lovelace Foundation Dr. Boothby will organize an aviation physiology laboratory that will work in cooperation with the physiology department of the University of New Mexico.

ITALY

Surgery of the Heart.—At a meeting of the medical academy *Filippo Pacini* in Pistoia, Prof. Piero Valdoni, who holds the chair of surgical pathology at the University of Rome, discussed surgery of the heart. This work, begun recently at the university, required various techniques, such as heart catheterization, study of oxygen in the blood, cardioangiography, use of the electro-ionic manometer, fluorocardiography, and ballistocardiography. To these studies were added capillaroscopy, examination of the fundus, examination of the circulating blood and the interstitial fluids, hemoglobin exchange, and sternal puncture.

Cardiosurgery has been of practical interest since Gross performed the first successful ligation of patent ductus arteriosus, some 10 years ago. The development of new methods today permits radical cure in some types of cardiac disease. Further progress will be obtained when the mechanism of the heart can be reproduced by a suitable apparatus, similar to those appliances suggested by Tosatti, Tonelli, and Provenzale.

These appliances oxygenate the blood of the vena cava, which is then poured back into the aorta. In this way the cardiopulmonary action could be substituted, and it would be possible to perform the operation on a bloodless organ. The practical realization of this system is still opposed by remarkable difficulties. The destruction of red blood corpuscles, which reaches 20%, must be eliminated; also removal of carbon dioxide from the blood must be effected. Prof. Valdoni explained then the technique to be followed in the treatment of stenosis of the aortic isthmus. He believes that one should operate on the patients soon, by resecting the stenotic portion and suturing the two ends.

Valdoni, in discussing congenital cardiopathies, classified them as cardiopathies with or without cyanosis and cardiopathies with late cyanosis. The tetralogy of Fallot has a higher incidence among the English-speaking population, while in Italy the Eisenmenger complex seems to be more frequent. The speaker had operated on 26 patients with Fallot's disease, with a death rate of 16%.

The diagnosis of pulmonary stenosis can be established safely by surgical exploration, i. e., by exposure of the right ventricle and lowering the finger into the pulmonary artery, which, being flexible, retroflexes and allows the exploring finger to reach the valvular orifice. The dilatation is performed after cardiac incision, with the use of dilators similar to Hegar's dilators or flat leaf-shaped dilators. In mitral stenosis the diagnosis may be made by means of digital exploration through the auricle, and the operation consists in the digital laceration of the commissures. Intervention is associated with the risk of mobilizing clots, which may result in the formation of emboli blocking the aortic bifurcation. Patients with severe decompensation and weak myocardium should not be operated on.

Ophthalmologic Association.—At the 43d general convention of the Swiss Ophthalmologic Association, Professors Bietti and Siliprandi of Pavia presented a report on experimental opacities of the crystalline lens produced by hypoglycemia. The speakers observed that within a few hours partial or total, unilateral or bilateral, opacities of the crystalline lens may result from injection of 8 to 10 mg. galegine (the active factor of Galega officinalis). These opacities can be observed in experimental animals; the opacities are present for a few minutes before death. The cataract develops more easily in rats made diabetic by the administration of alloxan. The production of the opacities seems to be due to the great hypoglycemic action of galegine, rather than to its toxicity. The phenomenon seems to be of osmotic origin and related to the compensatory increase of the sodium chloride content in the aqueous humor. Therefore, the process that leads to the cataract would be a late phase of the one leading to deficient refractive power in diabetics given too vigorous treatment. As a practical corollary to these animal experiments the speakers cautioned against treatment with insulin of diabetic patients who present an initial cataract.

Mechanism of Vitamin D_2 Action.—Dr. Candola presented to the Medico-Surgical Association of Pavia two papers on studies that he made on the mechanism of vitamin D_2 action in the therapy of cutaneous tuberculosis.

The first paper referred to the in vitro action of vitamin D_2 on the tubercle bacillus. The purpose of these studies was to ascertain whether this vitamin added to the culture medium is able to influence or to hinder the development of Mycobacterium tuberculosis. Kirchner's synthetic culture medium, to which normal human serum was added, was employed. The vitamin was added in quantities varying from 500 to 4,000 I. U. per cubic centimeter of culture medium.

The second paper was concerned with the action of blood serum of patients treated with vitamin D_2, on the development in vitro of Myco. tuberculosis. Influence of vitamin D_2 could not be shown on the development in vitro of Myco. tuberculosis, either when the vitamin was added directly to a culture or when it was introduced into the serum of the patients. The speaker concluded that the mechanism of vitamin D_2 action in the therapy of cutaneous tuberculosis remains obscure, but certainly it is not connected with a direct action of the drug on the bacteria.

NORWAY

The Future of the Medical Profession.—Dr. Peter M. Holst, who is at the head of a section of the Oslo City Hospital at Ullevaal, recently gave an address in which he discussed both the influence of compulsory health insurance on the nation and the outlook for the medical profession. He pointed out that compulsory health insurance has expanded enormously since 1912 and that no political party in the country is likely to oppose the fundamental principles on which it is based. He said, in effect: Norwegian doctors are so familiar with health insurance that they ought to be able to give an opinion on it. He claimed that voluntary health insurance is usually an expression of the qualities of responsibility and survival instinct, every wise and provident person being willing to offer much to avoid misfortune. But he queried the proposition that the same can be said of compulsory insurance, though he did not go so far as to insist that compulsory insurance has a directly destructive effect on these qualities. Norwegian doctors are, however, in possession of considerable experience giving support to the attitude of the medical profession in the United States. Dr. Holst pointed out that, though the expectation of life has constantly increased in Norway, there has been no corresponding reduction in the sickness rate, to judge by health insurance statistics. In Oslo, for example, the number of days for which monetary compensation was given for sickness rose per insured person from six in 1915 to 10 in 1947. The sickness rate in 1947 among some 41,000 male manual workers was nearly twice as high as it was among some 28,000 male office workers. The sickness rate was approximately 50% higher among women than among men, and among some 19,000 women manual workers it was about three times as high as among male office workers. The sickness rate was also much higher in the towns than in the country districts, and several times higher among persons enjoying compulsory insurance than it was among persons taking out voluntary health insurance. These great differences do not reflect, in Dr. Holst's opinion, any corresponding differences in actual sickness rates, but differences in the civic sense of re-

---

The items in these letters are contributed by regular correspondents in the various foreign countries.

sponsibility, giving support to the American point of view. Very many compulsorily insured persons seem inclined to exploit their rights to the utmost.

With regard to the future of the medical profession, Dr. Holst said that it has every reason to be gloomy, because there is a rapid deterioration of both economic and professional standards. At the present time "no doctor is able by his work as such to assure himself a care-free old age." Even those who can look forward to a pension in their old age know that it will be inadequate for the maintenance of their former standard of living. So many doctors are obliged to cling to a practice which gradually diminishes with advancing years. At the present time, some 10% of Norwegian doctors are over the age of 70; this percentage is bound to rise. The younger doctors who wish to specialize often find the road blocked by competition. In Dr. Holst's own section of the Oslo City Hospital, there were recently so many applicants for appointments to be held by would-be specialists that it would have taken some 10 years to give all of them their chance.

The Prognosis for the Tuberculin Convertor.—At what age does the conversion of a negative to a positive tuberculin reaction indicate the most sinister outlook for the person concerned? And is the outlook on conversion worse for a person living in contact with infectious cases of tuberculosis than for a person living in a nontuberculous environment? To answer these two questions, Dr. G. Hertzberg and Dr. L. Riddervold have undertaken much painstaking research in the tuberculosis department of the Oslo public health service, where they have scrutinized the records and cards of some 200,000 persons examined for tuberculosis between 1932 and 1948. In the course of this investigation, which was started in 1945, they have found 2,310 cases of definite tuberculin conversion, i. e., a change within a year from a negative Pirquet or Mantoux reaction to a positive Pirquet reaction. All these subjects were radiologically examined when conversion was found and later at regular intervals. After an observation period ranging from 1.9 to 4.5 years, the subsequent fate with regard to the outbreak of tuberculosis in these subjects was analyzed. It was found that the prognosis was worst for the persons whose conversion was discovered between the ages of 20 and 29. It was somewhat better between the ages of 13 and 19 and up to age 2 years. The prognosis was best between the ages of 3 and 12 years and comparatively good after the age of 30. As for the influence of an infectious tuberculosis environment on the prognosis, it was found to be worse for those with conversion who had been in contact with open cases of tuberculosis than for patients with conversion living in a tuberculosis-free environment. But this difference was definite only among subjects with conversion under age 20. Drs. Hertzberg and Riddervold have given statistical proof of conclusions which have hitherto been based mainly on general impressions derived from clinical experience. They are not, however, sure that, if their observation period were to be considerably prolonged, they would continue to arrive at exactly the same conclusions.

Death of Prof. P. Bull.—Prof. P. Bull, who died on Jan. 31, 1951, at the age of 81, enjoyed a world-wide reputation as a pioneer in surgery of the lungs. His four years of work at the turn of the century at the Pathological-Anatomical Institute in Oslo gave him a background of morbid anatomy which served him in good stead for the rest of his career. His doctorate thesis in 1905 dealt with teratoid tumors. In 1912 he was appointed professor of surgery; in 1918 he was elected a member of the Academy of Sciences, and in 1924 he became chairman of the Norwegian Medical Society. He was honorary member of several medical and surgical societies in the various Scandinavian countries and corresponding member of medical societies in Austria and France. The Association of Surgeons of Great Britain and Ireland and the Royal College of Surgeons of England made him an honorary member.

Prof. Bull's first thoracoplastic operation was performed in 1914. Thenceforth and till 1930, he continued to publish studies on this particular subject. In 1922, he was invited by the British Medical Association to lecture at Glasgow on extrapleural thoracoplasty for pulmonary tuberculosis. On this occasion he presented three patients whom he had brought with him from Norway. In the following year, he gave the opening address on thoracoplasty at a meeting of the Royal Society of Medicine in London. As far back as 1908, he began his campaign for immediate operation for acute appendicitis. His opponents were not only physicians but also some surgeons, and it took several years and many heated debates at meetings of the medical society to convince his critics of the errors of their ways. He was remarkably successful as a teacher, not least because he was never afraid of illustrating his arguments by the mistakes he had made himself. One of his biographers, Dr. Andreas Tanberg, has explained why Prof. Bull resigned his professorship of surgery as early as 1928, after he had held this appointment only 16 years. He took this step largely to escape having to act as an examiner two hours a day every day for three months in the year. Rid of his duties as teacher and examiner, he was free to take charge of the surgical department of a large hospital in Oslo.

ISRAEL

Foreign Student Problems of Hebrew University.—As in years past, the students from abroad who are attending the Hebrew University reflect, in part, the nature of the current immigration to Israel. Dr. Alexander M. Dushkin, dean of undergraduate studies, discussed some of the problems that have arisen in this connection and the steps taken by the university to deal with them. He said that those who admit the new students to the Hebrew University and give them counsel have been struck by the new types of student who have been coming from the Moslem countries and from behind the Iron Curtain, particularly from Iraq, Turkey, Egypt, Rumania, and Poland. Changes in student types are no new phenomenon at the Hebrew University. Every turn in the affairs of the Jews has been reflected in the type of students applying for admission. To that extent, at any rate, the Hebrew University has indeed been the university of the Jewish people.

The various new student types differ widely in cultural levels and backgrounds, in the content and quality of their education. American students, despite difficulties of language and unfamiliar academic mores, quickly "learn the ropes." The students from behind the Iron Curtain who have been trained in the communist school program, bring with them an education that is uneven and "spotty." But their academic habits seem to be essentially sound, and they, too, adapt themselves readily to university study. The Iraqis, on the other hand, present a special problem; with some notable exceptions their academic standards are low and their work habits poor.

Whatever differences exist among the new foreign students, they are nearly all, unfortunately, ignorant of Jewish life and culture. This year a small but growing number of Druze and Arab (non-Jewish) students have enrolled at the university, with no knowledge of Jewish matters. Were the Hebrew University to follow the practice of other universities, these students would be required to prepare themselves adequately outside the university, at least in the Hebrew language. But the Hebrew University, like the Jewish state, is committed wholeheartedly to facilitate free, unlimited immigration, to encourage students from abroad, and to give equal opportunities to all students, Jewish and non-Jewish. Consequently the problem of preparing these students must be met by the university itself.

Medical Students Graduate.—The first 14 medical students to graduate from the Hebrew University have completed their internship at the Beilinson Hospital and have begun to practice as private physicians or as members of medical institutions.

Hypopotassemia and Insulin.—The relation between potassium content of the blood and the metabolic changes in diabetes under the influence of insulin has been repeatedly described. In a clinical paper, S. Brandstetter (*Harefuah*, March 15, 1951) reports, for the first time in Isreal, a particularly characteristic case. A woman, 58, with diabetes of 21 years' duration, was admitted to the hospital in diabetic coma with blood sugar of 871 mg. per 100 cc. After administration of 660 units of insulin during the first 24 hours and 7,600 cc. of isotonic sodium chloride by infusion, the blood sugar was reduced to 200 mg. per 100 cc. The patient regained consciousness, but severe asthenia and dyspnea developed. Difficulty of movement resembled a cataleptic state. Breathing was very feeble. The potassium level on admission was 17 mg. per 100 cc.; after the patient regained consciousness, it fell to 6.8 mg. Oral administration of 11 gm. of potassium chloride fully changed the clinical picture; movements were again normal, and breathing was regular. Hypopotassemia in diabetic coma is probably caused by potassium leaving the cell and entering the blood serum, whence it is excreted by the kidneys. Inappetence and vomiting further alter the potassium level. In this connection, the report of Dr. Groen, Amsterdam, a guest lecturer at the medical school in May, 1951, is of interest. He showed that, in the isolated diaphragm of the living rat, glucose utilization as well as potassium uptake is increased by addition of insulin.

National Social Insurance Plan.—The draft of a new social insurance scheme, to cover more than one million persons by the end of 1953, has been completed and is to be submitted to the cabinet within the next few days. The scheme, which under the proposed law is to be administered by a National Social Insurance Authority, will provide free medical service and hospitalization to the insured and their dependents; maternity benefits; old age, widow, and orphan pensions, and disability benefits for persons unable to continue work for reasons of health.

According to the draft, the scheme is to be implemented in three stages. The first phase, due to come into force in October, 1951, will extend compulsory insurance to all wage and salary earners and members of cooperatives and will cover about 300,000 persons (including dependents, about 600,000 persons). The second phase, which will go into effect by June, 1952, will cover all self-employed persons (e. g., craftsmen, shop owners). The third phase will provide for compulsory insurance of the entire population, for old age, widow, and orphan pensions. Taking into account the anticipated increase of population, the scheme will by that time cover 450,000 directly insured persons representing, with dependents, a population of more than a million.

Maternity benefits will include free hospitalization, 12 weeks' paid leave, and a layette for directly insured women. Wives of insured persons will receive the same benefits but with paid help for the household in place of the paid leave granted to insured women. Sickness benefits include medical care and rehabilitation. Pensions will be granted in cases of incapacity and will be calculated according to the degree of disability and size of family without reference to previous salary. Old age pensions will be at a flat rate.

It is anticipated that insurance subscriptions will be paid into the Insurance Authority, which will then settle the expenses of the various existing sick funds providing the medical services. The authority will take over work accident insurance from the private insurance companies and will also directly disburse all payments and benefits made under the scheme.

Work on the scheme began about two years ago, when the "Kanev Committee" was appointed to prepare a social insurance plan. The recommendations of the Kanev Committee were studied by the government in March, 1951, and passed to a second committee. It is anticipated that the present expenditure of IL. 25m. on various types of social insurance will be sufficient to cover the charges of the new scheme and that no additional burden will be placed on the national economy or the treasury.

New Hospital for Crippled Children.—The Society for Crippled Children recently opened a new hospital in the Katamon quarter of Jerusalem. The site was provided by the government, while the cost of building repairs was borne by the society with the help of donations. The new hospital, under the medical management of Dr. E. Heilbronner, has 35 beds. It provides treatment and accommodation for victims of poliomyelitis. Another wing is under construction, which will increase the number of beds to 65 and ultimately to 100. The official opening will take place as soon as the installation of the new medical equipment and furniture is completed.

CORRESPONDENCE

NATIONAL CANCER INSTITUTE

To the Editor:—I wish to compliment the American Medical Association for its Special Bulletin No. 1, containing Mr. George E. Connery's excellent account of our activities in Bethesda titled "A Report on the National Cancer Institute." I note an omission, however, which I believe should be incorporated in the report in order to indicate the complete scope of the program of the institute. We have two clinical research programs, one at the Laboratory of Experimental Oncology in San Francisco and the other at the United States Marine Hospital in Baltimore.

The Laboratory of Experimental Oncology, of which Dr. Michael B. Shimkin is chief, is a cooperative project on neoplastic diseases with the University of California School of Medicine. With the cancer patient as the focal point of investigation, the work of this laboratory is oriented along four broad approaches: (1) experimental therapy, providing clinical material for other studies as well as permitting evaluation of such procedures on neoplastic diseases; (2) physiology, particularly cardiovascular and respiratory physiology of patients with neoplastic diseases; (3) biochemistry, including metabolic studies on cancer patients, and investigations of specific biochemical reactions, and (4) the study of protein fractions of cancer and normal tissues of human and animal origin, utilizing physicochemical and immunochemical techniques.

Some of the experimental therapy projects now being investigated at the Laboratory of Experimental Oncology concern the effect of virus infections on neoplastic growth, therapy of inoperable visceral and regional metastases by intra-arterial catheterization, and evaluation of nitrogen mustard, triethylene melamine and other materials in the treatment of clinical cancer. Among other contributions to knowledge of cancer, clinical studies by this group have clarified the role of blood histamine in myelogenous leukemia, have added information on the fate of normal and leukemic white blood cells, and have shown that the sulfhydryl content of blood is significantly reduced in patients with cancer.

The second clinical program includes a cooperative study of chemotherapeutic agents with the Tumor Clinic of the United States Marine Hospital in Baltimore. Dr. Ezra M. Greenspan, who heads this program, is investigating new chemotherapeutic and diagnostic methods in tumor patients, conducting metabolic and biochemical studies in patients and animals after administration of potential carcinolytic substances, and studying the mechanism of action of established anticancer agents in experimental animals.

Director, National Cancer Institute,
U. S. Public Health Service,
Bethesda 14, Md.

RUTABAGAS, TULIP BULBS AND GOITER

To the Editor:—In the editorial "Nutrition and Goiter" (*J. A. M. A.* **145**:824 [March 17] 1951) there appeared the statement "Also in the same country, monks who subsisted on rutabagas and tulip bulbs were found to have developed goiter." The authority given was Greer (*Physiol. Rev.* **30**:513, 1950), thus giving the reader the impression that Greer had himself made this observation. Actually, he relied on the report by Astwood of a communication said to have been made to the latter by H. P. Himsworth, of London, who is said to have seen the monks. A somewhat different account is given by Means (The Thyroid and Its Diseases, ed. 2, New York, n. d., p. 189). In that, an unnamed Belgian colleague of Dr. Himsworth is made accountable for the story and the monks are said to have had little but rape seed and cabbage.

New York.

BUREAU OF MEDICAL ECONOMIC RESEARCH

SURVEY OF PHYSICIANS' INCOMES

Frank G. Dickinson, Ph.D.
and
Charles E. Bradley, Ph.D., Chicago

In April, 1950, the Bureau of Medical Economic Research of the American Medical Association and the Office of Business Economics of the United States Department of Commerce jointly initiated a survey of the 1949 incomes of physicians from professional services, excluding incomes from other sources. The first report on this survey was published this week in the July, 1951, issue of the *Survey of Current Business*, United States Department of Commerce.[1] The tabulations and interpretations in that current article are the responsibility of the Department of Commerce although the Bureau of Medical Economic Research was given the opportunity to comment on the manuscript of the article prior to its publication. The designing of the questionnaires, the selection of samples of physicians by name, and the mailing of the questionnaires was a joint responsibility. Later on, all of the returned questionnaires will be sent to the Bureau of Medical Economic Research for further study and analysis. From the very inception of this joint undertaking a fine and genuine spirit of cooperation and mutual criticism has prevailed between the staffs of the Bureau of Medical Economic Research and the Office of Business Economics.

We want to thank the more than 55,000 of the 125,000 physicians who received questionnaires for taking the time and trouble to fill out and return the schedules. This remarkable and unprecedented number and percentage of returns in a survey of professional incomes has exceeded all expectations and gives the study an importance unique in the history of mail income surveys. We should also like to thank the officers and editors of state and county medical societies for their assistance.

THREE QUESTIONNAIRES

Three questionnaires were employed. A white form was sent without a follow-up to 100,000 physicians—virtually every other name in the punch-card files of the Bureau of Medical Economic Research. Our basic reason for sending out so many white questionnaires was to provide a large body of data without resorting to follow-up mailings. Some 42,000 of these were returned but approximately 12,000 returns were excluded from this first analysis because they came from retired and other physicians not in practice, interns, residents and fellows-in-training, military physicians, and physicians whose major source of income was from a medical school or because they were defective; these groups of physicians were to be excluded from the study but their names could not be removed from the original mailing lists.

A buff-colored questionnaire, identical in form with the white questionnaire, was sent to 10,000 physicians selected at random from among those who did not receive white questionnaires. On the outside of the return envelope was the serial number which the Bureau of Medical Economic Research has assigned to that particular physician. By checking off these code numbers in the Department of Commerce as the returns were received, it was possible for the Bureau of Medical Economic Research to address two follow-ups to those who did not respond to the first mailing; this procedure also protected the secrecy of the returns. Except for the "Technical Notes" at the end of his article, Weinfeld makes no reference to the data derived from the buff questionnaires. When we obtain the returned questionnaires from Washington we shall check them against our completed punch-card files in order to determine the representativeness—group for group, not person for person—of the returned buff questionnaires against the universe of the 10,000 physicians to whom they were mailed. In addition, we hope to obtain an almost 100 per cent response to the same income questions from a small random sample of the physicians who did not reply in order to compare the new data with the data on the buff questionnaires which have already been returned to the Department of Commerce. When this step is finished, we shall have a great quantity of information with which to check the tables prepared by Weinfeld. This division of labor was agreed upon before the survey started.

A green questionnaire was sent to 15,000 physicians selected at random from those who did not receive either a white or a buff questionnaire and the code number procedure was employed for the purpose of addressing two follow-ups. The green questionnaire requested data for the years 1945 through 1948 in addition to 1949; the Office of Business Economics needed these data for 1945-1948 for other statistical series.

Thus this article in the current issue of the *Survey of Current Business* has an extremely broad base. On these grounds alone this survey is not in the traditional small sample category; roughly, two out of five physicians responded.

It is very difficult to provide a brief summary of this long article with its 23 tables and three charts. In a word, this study indicates that the average physician has been moving up the inflationary ladder about as rapidly as the average American.

GENERAL AVERAGES

The average (mean) 1949 net income from medical practice of the 30,000 physicians whose returned questionnaires were analyzed was $11,058—see row 1, Table A. This was 60.4% of the average (mean) gross income of $18,316. The median net income reported was $8,835; that is, one-half of the physicians reported net incomes of less than $8,835 and one-half reported higher incomes. These are the two over-all averages to be kept in mind. They are based on all replies, which means that they came from physicians of all classes and types except the excluded classes noted above; for convenience we shall use the term "all" physicians in referring to data from the 30,000 replies. In this summary we shall stress the means, although many statisticians will consider the medians more representative values in the various distributions of physicians' incomes.

Of the 30,000 physicians reporting, 23,000 were in independent practice (derived more than 50% of their professional income from fees from independent practice); their mean net income in 1949 was $11,858 and their median income, $9,668. The remaining 7,000 of the 30,000[2] were engaged in salaried practice (received less than 50% of their professional income from fees); their mean net income was $8,272 and their median net income, $7,555.

The 30,000[2] replies were also separated into three categories: (1) non-salaried practice (20,000 returns) for which the mean was $11,744 and the median, $9,561; (2) part-salaried practice (5,000 returns) for which the mean was $10,928 and the median, $8,760; and (3) all-salaried practice (5,000 returns) for which the mean was $8,434 and the median, $7,678.

Before further major breakdowns of the data are presented, several historical comparisons may be useful in providing a general setting. Since more data from the past are available for non-salaried physicians, who in 1949 reported higher average net incomes than did all physicians, the historical comparisons, although limited, can best be made of their incomes. On the basis of Department of Commerce surveys for 1935-1939, Weinfeld concludes that the mean net income of non-salaried physicians was 186% higher in 1949 ($11,744) than in the period 1935-1939 ($4,100), the most frequently used base period in economic reports. Because the incomes of salaried physicians have apparently not risen as rapidly since the base period as the incomes of independent physicians, it follows that the in-

Director (Dr. Dickinson) and Associate in Economics (Dr. Bradley), Bureau of Medical Economic Research, American Medical Association.

[1] Weinfeld, William: Income of Physicians, 1929-49. A reprint of this article from the Survey of Current Business may be obtained without charge from the Bureau of Medical Economic Research, American Medical Association, 535 N. Dearborn St., Chicago 10.

[2] Precisely, the total number of returns analyzed was 29,878 and the two groups numbered 23,213 and 6,665, not 23,000 and 7,000. Of the larger group, 3,307 derived some—but less than 50%—of their income from salaries; and 1,706 of the smaller group derived more than 50% but less than 100% from salaries. The sum of these two part-salaried groups equals 5,013. Hence the non-salaried numbered 19,906 (23,213 minus 3,307), the part-salaried, 5,013, and the all-salaried, 4,959 (6,665 minus 1,706).

crease in the incomes of all physicians was less than 186%. On the basis of limited data we would estimate that the mean net income of all physicians in 1949 ($11,058) was roughly 150 to 170% above that in 1935-1939 (between $4,100 and $4,400). The national income of the American people was 224% higher in 1949 than in the period 1935-1939; the national income per capita was 179% higher. The increase in the national income when adjusted for the number of persons in the working force—commonly called the number gainfully employed—was 177%. (Some economists might prefer the smaller national aggregate known as personal income as a frame of reference; personal income per capita in 1949 was 159% higher than in 1935-1939.) It appears quite clear that the rise in the incomes of physicians and of the American people—their patients—have kept pace with each other during the 1940's. The average physician has been traveling near the center of the inflationary highway up which the entire American economy has been moving since before World War II. Such is the over-all picture presented by the current survey of physicians' incomes in relation to the general level of income of the American people. Whether physicians' incomes were too high or too low in 1935-1939 has not been determined and, possibly, never will be determined to the complete satisfaction of all people. How much was "too high" or "too low" in 1935-1939? An answer would require almost endless consideration of the alternative economic opportunities of high school graduates of equal talents, the personal and economic sacrifices during 8 to 13 years of premedical and medical education and training, the long work week of practitioners, the economic equivalent of the personal satisfaction of helping restore sick people to health. These considerations are largely beyond the scope of our present interest.

The most comprehensive previous study of the incomes of physicians was by Leven for 1929.[3] Accordingly, Weinfeld chose to use 1929 in most cases as his base year despite the fact that economists generally consider 1929 "over the hill and far away" for any purposes of historical comparisons. To our knowledge, no agency of the Federal Government is currently using 1929 as a base period in its economic reports. The available data on physicians' incomes for 1929 are, however, of bench-mark stature; they are far superior to the data available for 1935-1939, particularly with regard to specialists. This situation presented the Office of Business Economics with a difficult choice. A reasonable compromise would have been for Weinfeld to use 1929 for internal comparisons between classes of physicians and 1935-1939 for comparisons between the incomes of physicians and the American people—their patients. The general picture, however, is about the same if 1929 instead of the customary 1935-1939 is used as the base period. The mean net income of all civilian physicians increased by 108%, from $5,304 in 1929 to $11,058 in 1949; the increase for all earners in the general population was 109%.

According to the U. S. Bureau of Labor Statistics, the fees of physicians were 38% higher in 1949 than in the base period 1935-1939.[4] This index of physicians' fees is part of the Consumers' Price Index—formerly known as the Cost of Living Index—which is so widely used in making wage adjustments. The entire index for 1949 was 69% above the base period.

Obviously, an increase of 150% or 160% or 170% in the average incomes of physicians since the base period cannot be attributed to a general rise in fees alone. Two other factors, which we believe are probably more important in accounting for this increase in physicians' incomes, are: (1) improved collections—a decrease in the percentage of uncollected bills for medical services rendered and, perhaps, a smaller percentage of charity patients to whom services were given free or at reduced fees; (2) greater "output per physician." These data on the incomes of physicians clearly indicate that 1,000 physicians were doing considerably more medical work in 1949 than 1,000 physicians did a dozen years ago. This increase in "output per physician" resulted from, among other things, changes in therapy and diagnosis, increased use of technical assistants, seeing a higher proportion of patients in the office and in the hospital, and improved transportation.

TABLE A.—*Average Gross Income and Net Income of Physicians by Source of Income, 1949*

Group of Physicians [1] and Number *of Replies Analyzed*	Mean Net Income (1)	Median Net Income (2)	Mean Gross Income (3)	Median Gross Income (4)	Percentage of Replies (5)
1. "All" Physicians (29,878)	$11,058	$8,835	$18,316*	$14,829*	100.0%
2. Independent Physicians (23,213)	11,858	9,668	......	......	77.7
2a. General Practice	8,835	7,428	......	......	(32.1)
2b. Partly Specialized	11,758	9,902	......	......	(14.1)
2c. Fully Specialized	15,014	12,599	......	......	(31.5)
3. Salaried Physicians (6,665)	8,272	7,555	......	......	22.3
3a. General Practice	6,281	6,132*	......	......	(2.8)
3b. Partly Specialized	7,135	6,693	......	......	(2.2)
3c. Fully Specialized	8,884	7,953	......	......	(14.4)

4. Non-Salaried Physicians (19,906)	11,744	9,561	19,710	16,108	66.6
5. Part-Salaried Physicians (5,013)	10,928	8,760	12,781	8,993	16.8
6. All-Salaried Physicians (4,959)	8,434	7,678	......	......	16.6

Source: Weinfeld, William: "Income of Physicians, 1929-49," **Survey of Current Business**, July, 1951, U. S. Department of Commerce, Tables 2, 3, 6, 7, and 9.

* Hitherto unpublished data from the joint Department of Commerce/American Medical Association 1950 income survey of the medical profession. These data were eliminated from the Weinfeld article because of lack of space. We have also quoted a few figures in the text which were deleted from Weinfeld's tables in the final editing.

1. The group "all" physicians (row 1), including salaried as well as independent practitioners, excludes interns, residents, fellows-in-training, physicians in military service, and medical school personnel. All replies (row 1) were classified into two groups (rows 2 and 3) and then reclassified into three groups (rows 4, 5, and 6). Independent physicians (row 2), that is, physicians in independent practice, are those whose major source (more than 50 per cent) of medical income is fees from independent practice; they include (*a*) all non-salaried physicians (row 4) and (*b*) those of the part-salaried (row 5) whose major source of income is fees from independent practice. Salaried physicians (row 3), that is, physicians in salaried practice, are those whose major source of medical income is from salaried practice; they include (*a*) all of the all-salaried physicians (row 6) and (*b*) those of the part-salaried physicians (row 5) whose major source of income is from salaried practice.

REACTIONS OF PHYSICIANS

Doubtlessly, the reactions of physicians to the average incomes given in this summary and to the many more given in in the article in the *Survey of Current Business* will vary considerably. Physicians who were practicing in 1935-1939 and who are now approaching the peak earning period of their lives, around age 50, will probably contend that these reported over-all averages ($11,058 and $8,835) are too low. On the opposite side will be physicians who were in their fifties a dozen years ago and are now well past the peak earning period of life; their incomes have increased, on the average, far less than 150% to 170% since 1935-1939. On the whole, physicians who are now at or near the peak earning period of their lives will regard the averages as too low and older physicians will probably think they are too high. Likewise, many specialists will regard the over-all averages as too low and many general practitioners will consider them too high. Such are the limitations of any over-all average. The averages for each of the various groups of physicians will probably seem more reasonable to most physicians in each group. In thinking about the rise in their own incomes, many physicians will forget that the national income also rose until it was three and one-fourth times as great in 1949 as in 1935-1939. Only by comparing the increase in the incomes of the members of their profession with that of the American people taken all together can physicians get any real perspective on their relative position in a rapidly changing economy.

[4] Dickinson, F. G.: Medical Care Prices Vs. Cost of Living, J. A. M. A. **143**: 1198-1199 (July 29) 1950. Reprinted as Bulletin 76, Bureau of Medical Economic Research, American Medical Association, Chicago, 1950. In addition to fees and net incomes, other factors should be considered by a physician in estimating his slice of prosperity. They, like other citizens, are inclined to ignore their share of the increasing liability of citizens for the national debt in estimating their net worth. Bulletin 65, "How Rich Are You?" (Bureau of Medical Economic Research, American Medical Association, 1948), describes a method by which physicians and others can estimate their family's share of the burden of the federal debt.

The concept of the average income of the members of a clearly defined group is useful in making historical comparisons. On the other hand, the concept of the income of the average member of that group is very misleading because no person can remain at the same age as time passes. Two illustrations, based on Weinfeld's Table 16, can be used to show that the concept of the average physician must be used very carefully by any physician who seeks to check the changes in his own income during the past 20 years with the averages developed in this and earlier surveys of the incomes of physicians by the U. S. Department of Commerce.

Consider a physician who was just under 30 years of age in 1929 and hence almost 50 years of age in 1949. The average net income of physicians in independent practice in the age group 45-49 in 1949 was somewhat more than twice as great as the average of those in the under-age 30 group. If we assume that this age-earnings relationship has held true since 1929, this physician could have expected his net income for 1949 to have been about twice as great as his net income in 1929 providing he had enjoyed the average gain due to 20 years of experience in the practice of medicine. His income would not have kept pace with the average of his medical school classmates if it had not doubled between 1929 and 1949. In addition to the age-earnings progression of his profession, there is a second factor which should have increased his income—the general increase in the average income of the American people which, on the average, doubled between 1929 and 1949. As already noted the average income of physicians also doubled. (If the average income of all physicians—and of the American people—had remained unchanged, this second factor could, of course, be ignored in our illustration.) On the basis of these two factors combined, the income of this physician should have quadrupled between 1929 and 1949 ($2 \times 2 = 4$).

Now consider a physician who was in his late forties in 1929. In his age-earnings progression Weinfeld groups all physicians 65 and over into one class. On the basis of this age-earnings progression we can assume that the average physician's income at age 67 is about half as high as the average for age 47. This second physician, who at age 47 in 1929 was at or near the peak earning period of his life, should have earned one-half as much in 1949 as he did in 1929 under the assumptions regarding the age-earnings progression already noted above. During those 20 years, however, the average incomes of the American people and of all physicians doubled. Hence, these two factors cancel out, indicating no difference between his 1929 and his 1949 income ($\frac{1}{2} \times 2 = 1$).

These two illustrations were chosen as extreme cases in order to show the differences between physicians who were at their peak earning period of life in 1949 and in 1929. Any particular physician who attempts to use this new survey of physicians' incomes as a means of determining whether his income was above or below average in 1949 should separate these two economic factors in making any computation for himself. He should examine Weinfeld's tables 8, 16, and 18 which show the averages by age groups. Unfortunately only a few comparable averages by age groups for 1929 were developed by Leven[5] and none are available for 1935-1939. If such averages were available by age groups, a physician at any age could easily determine how near his 1929, 1935-1939, and 1949 net incomes were to the average for his attained age group in each of these years.

AVERAGE GROSS INCOMES

The gross income corresponding with $11,058, the average net income of all physicians, was $18,316; thus, the net was 60.4% of the gross. The relationship between the net and gross incomes of non-salaried physicians is probably more significant; the net was $11,744, 59.6% of the gross, $19,710. Weinfeld notes a slight rise in the general cost of conducting a medical practice, from 36.7% of gross in 1945 to 40.4% in 1949. Payroll expense alone rose from 11.1% to 13.2%. The remainder of the 40.4% in 1949 was paid to business firms for drugs and supplies and for such other items as transportation (automobile, train) and rent. More generally, the average physician realizes about three-fifths of the fees paid to him by his patients and the other two-fifths is paid out by him to other income receivers. Hence, our principal interest in this summary, as well as in the article itself, is in net income and not in gross income. Some day we hope to make a survey of the personal consumer expenditure patterns of physicians. We suspect that the percentages spent for homes and automobiles are high and the percentages spent for other items, e. g., tobacco and recreation, are low relative to the expenditure patterns of all families in the same income class. This peculiar pattern may reflect the long work week of the physician.

INCOMES OF LAWYERS AND DENTISTS

The mean net income of non-salaried lawyers rose from $5,534 in 1929 and $4,363 in 1935-1939 to $8,083 in 1948, increases of 46% and 85%, as compared with the increases of 125% and 186% for non-salaried physicians.[6] The present survey is the first which clearly indicates that the average incomes of physicians are now above those of lawyers. Studies covering the late 1920's and early 1930's placed the lawyers' incomes above the physicians'. The mean net income of non-salaried dentists rose from $4,267 in 1929 and $2,812 in 1935-1939 to $7,146 in 1948, increases of 67% and 154%.[7] Apparently there has been no counterpart in the practice of law or dentistry of the so-called wonder-drug revolution of the last decade and a half in the practice of medicine. Rapid changes in diagnosis and therapy have unquestionably increased very sharply the demand for the services of physicians.

The expected data on the average hours of work per week for physicians, required for the comparisons of income per hour, are not now available. Hence, no comparisons of hours worked and of earnings per hour in these three professions can be presented. The comparisons of these incomes of physicians, lawyers, and dentists are of some significance today but much more significant comparisons of the major professions can be made after future surveys of the incomes of certified public accountants and consulting engineers have been made; these two professional groups outranked physicians and lawyers in earlier studies of the incomes of these five major professional groups.[7]

Our major interest in this summary of the article is the relationship between the trends in the incomes of physicians and of the American people—their patients. For several reasons Weinfeld has a greater interest in comparing the incomes of the different professions; these reasons are closely related to the particular function of his studies for the Office of Business Economics. Although the study has been clarified by the exclusion of interns, residents, and fellows-in-training, we believe that these physicians should be included when comparing the over-all average incomes of physicians with those of lawyers and dentists because the latter two professions do not have any comparable group which could be excluded from surveys. These physicians, under the supervision of senior physicians in hospitals, are providing a very large amount of medical care to the American people. Their monthly salaries are nominal. As noted by Weinfeld, if they had been included in the survey the average net income of all physicians would have been perhaps 10% lower, say about $10,000 instead of $11,000. It is especially *necessary to make this allowance in comparing the three professions* because young lawyers and young dentists were included in the surveys of incomes of lawyers and dentists. At least the comparisons should have been age for age. We wish to make it clear, however, that for all other purposes we thought that the decision to exclude interns, residents, and fellows-in-training was proper.

---

[5] Op. cit. p. 114. He presented average gross incomes by years of practice instead of by age groups.

For earlier comparisons of the incomes of these five professions, see Friedman, M., and Kuznets, S.: Income from Independent Professional Practice, New York, National Bureau of Economic Research, 1945.

INCOME AFTER TAXES

Net incomes before and after federal taxes are two quite different amounts. The increase since 1935-1939 in mean net incomes overstates the gain in mean net incomes after federal income taxes. Because physicians, like other citizens, are required to pay federal income taxes, it is proper to mention the peculiar economic pattern of the life of the physician. After spending a long time in training, any professional man starts to earn late in life and his lifetime earnings are bunched into a relatively short period of time. Because income tax rates are steeply progressive he will pay more taxes during his lifetime than another person who earns exactly the same amount of money during his life, spread over a longer working lifetime—as much as 10 years longer than the working lifetime of the typical physician. Because of the lack of precise data for the base period, 1935-1939, we can make only general comments about the probable increase in the mean net income after taxes. We have, however, estimated that, assuming a wife and two other dependents, the amount of income taxes on 1949 incomes averaged about $1,300 per physician as compared with less than $100 of taxes in the base period, 1935-1939. It should be abundantly clear that the increase in the net income after taxes between 1935-1939 (and 1929) and 1949 was far less than the increase reported in the article for mean net incomes before taxes.

THE ALL-SALARIED VERSUS THE NON-SALARIED

As previously noted, the mean net income for 1949 of physicians who derived all of their professional income from salaried practice — the all-salaried physicians — was $8,434 as compared with the mean of $11,744 for those in non-salaried practice. *The difference of $3,310, uncorrected for age differences,* must be examined. The non-salaried physician is roughly comparable to a small retailer; as such, he is a prime risk-bearer in our economy. Accordingly, inflation and prosperity raise his income more sharply than the salary of the all-salaried physician; and vice versa in depression. The excess in the average number of hours worked per week by the non-salaried above the average worked by the all-salaried physicians is not now available. In addition to less exposure to the business cycle, the *all-salaried physicians have certain financial advantages* which are not reflected in their cash compensation. Among these are various provisions for vacations, sick leave, insurance, and, perhaps most important, pensions. The non-salaried physician, whether he is an individual proprietor or a partner, cannot use any of his gross income to purchase an annuity or pension for himself because he does not qualify under the employer-employee relationship defined in the Federal Income Tax Law. On the other hand, the physician who is employed can have a pension financed in whole or in part by his employer out of his employer's gross receipts. This pension benefit does become taxable to the all-salaried physician when he retires; the extra benefit is merely a tax deferment which will enable him to pay the tax on this benefit during his retired years when, presumably, the income tax rate will be lower for him because his income is lower. It is impossible, however, to assign a specific amount of the $3,310 difference to this pension advantage[8]; our best guess would be one-fourth. Vacation pay and sick leave benefits could account for a similar fraction of this difference of $3,310.

TABLE B.—*Average Net Income of Physicians by Region, 1949*

Region	Physicians in Independent Practice		Physicians in Salaried Practice		Non-Salaried Physicians	
	Mean (1)	Median (2)	Mean (3)	Median (4)	Mean (5)	Median (6)
1. New England	$ 9,740	$ 8,061	$8,605	$7,597	$ 9,602	$ 7,816*
2. Middle East	10,270	8,263	8,026	7,562	10,130	8,157*
3. Southeast	12,157	9,855	7,616	7,333	11,958	9,602*
4. Southwest	13,243	11,402	8,604	7,545	13,179	11,320*
5. Central	12,755	10,743	9,115	7,879	12,631	10,674*
6. Northwest	12,313	10,632	7,808	7,283	12,305	10,678*
7. Far West	14,368	12,178	7,807	7,409	14,235	12,243*
8. United States	11,858	9,668	8,272	7,555	11,744	9,561

Source: Weinfeld, Tables 10 and 12.

* See footnote (*) to Table A.

The states included in each of the seven regions are **New England:** Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, Vermont; **Middle East:** Delaware, District of Columbia, Maryland, New Jersey, New York, Pennsylvania, West Virginia; **Southeast:** Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, South Carolina, Tennessee, Virginia; **Southwest:** Arizona, New Mexico, Oklahoma, Texas; **Central:** Illinois, Indiana, Iowa, Michigan, Minnesota, Missouri, Ohio, Wisconsin; **Northwest:** Colorado, Idaho, Kansas, Montana, Nebraska, North Dakota, South Dakota, Utah, Wyoming; **Far West:** California, Nevada, Oregon, Washington.

SPECIALISTS VERSUS GENERAL PRACTITIONERS

The reported mean net income of general practitioners in independent practice for 1949 was $8,835, for partly specialized (part-time specialists), $11,758 and for fully specialized (full-time specialists), $15,014. Thus the mean net income of the partly specialized physicians was almost the same as the mean net income of all physicians in independent practice (physicians whose major source of income was fees)—$11,858, as already noted; in that sense, he is an average physician. The spread of about $6,200 between the averages for general practitioners and fully specialized physicians will be of great interest to all members of the medical profession. Weinfeld notes that the spread was considerably smaller percentagewise in 1949 than in 1929 and only $100 more. This important finding is also presented in one of his charts.

Elsewhere[9] we have estimated that the accumulated investment of an intern in his seven or eight years of premedical and medical education and in income sacrificed is well over $30,000. The intern contemplating the three or four years of residency training necessary to become a specialist must reckon with the economic aspects of an additional investment. The income margin between specialists and general practitioners may or may not have a dollar value sufficient to offset the extra financial sacrifice during three or four years of additional training at nominal salary, or the personal sacrifice at a time in life when most young men are starting or have already started to have a family. Furthermore, *the tendency of specialists to locate in* the larger cities where family living costs are higher may offset some of the extra earnings of specialists. Professional qualifications, interests, and prospects may outweigh these economic considerations in the decision to become or not to become a specialist. We shall defer comment until we know the differences in the age distribution of general practitioners and fully specialized physicians which could account for some of the difference in the mean net incomes.

---

[8] Under the leadership of a special committee of the American Bar Association, a bill (H.R. 4371) was introduced recently in Congress for the purpose of correcting this tax inequity for all self-employed. This inequity is especially great in the professions because of the long period of training and subsequent relatively high incomes—and physicians have a much longer training period than other professional men.

[9] Dickinson, F. G.: Income Tax Discrimination Against the Professions, J. A. M. A. **142**: 1357-1360 (April 29) 1950. Reprinted as Bulletin 74, Bureau of Medical Economic Research, American Medical Association, Chicago, 1950.

REGIONAL VARIATIONS

We turn now to certain important breakdowns of the quantity of data presented in this current article. As already noted, the mean net income of non-salaried physicians in 1949 was $11,744 and the median, $9,561. The regional differences are shown in Table B for physicians whose major source of income was fees from independent practice, for physicians whose major source of income was from salaried practice, and for physicians whose entire source was from independent practice (non-salaried physicians). The non-salaried physicians in the Far West (Washington, Oregon, Nevada, and California) reported the highest mean and median net incomes, $14,235 and $12,243. New England ranked lowest in both mean and median incomes, $9,602 and $7,818. We are now dealing with a part of the universe of our responses and many questions can be raised regarding the representativeness of the returns from each of these seven regions. Weinfeld tested each area by median age and found no striking incongruities.

Unfortunately, the Bureau of Medical Economic Research was not able, at the appointed time, to provide the Office of Business Economics with the data on age breakdowns necessary to eliminate that factor through the customary statistical procedure of age standardization. For this reason our criticism and skepticism regarding regional and other breakdowns of the data should not be considered a reflection on the Office of Business Economics and Mr. Weinfeld, but a confession of our own inability to provide the assistance which we had hoped we would be able to give at the time needed. We expect later to make many of these corrections for variations in age which could, of course, account for some of the regional differences between the mean and median net incomes in New England and the Far West. On the other hand, the rate of population and economic growth of an area has a great deal to do with the average earnings of physicians and of most income earners.

TABLE C.—*Average Net Income of Physicians by Size of Community, 1949*

Size of Community (Population)	"All" Physicians Mean (1)	"All" Physicians Median (2)	Physicians in Independent Practice Mean (3)	Physicians in Independent Practice Median (4)	Physicians in Salaried Practice Mean (5)	Physicians in Salaried Practice Median (6)	Non-Salaried Physicians Mean (7)	Non-Salaried Physicians Median (8)
1. Under 1,000	$ 7,090	$ 6,177	$ 7,109	$ 5,699	$7,019	$7,000	$ 7,029	$ 5,606*

Source: Weinfeld, Tables 10, 14 and 15.

* See footnote (*) to Table A.

Weinfeld also presents tables showing mean and median net incomes for individual states. For physicians in independent practice the three highest means were for Arizona, Washington, and California; the three lowest, for Vermont, Maine, and Arkansas. For physicians in salaried practice the three highest means were for Minnesota, North Dakota, and New Hampshire; the three lowest, for Nevada, Nebraska, and Kentucky. Since it was not possible for Weinfeld to make more than general tests of the representativeness of the returns from each state, we shall withhold comment on these state differences and rankings until we have had an opportunity to check the data against our punch card file for physicians, which is nearing completion. For the same reason we shall withhold comment on Weinfeld's table of estimates, by states, of personal consumer expenditures for physicians' services. Although there has been considerable demand for these state breakdowns on personal consumer expenditures, we are somewhat skeptical about the validity of the differences between states and of the absolute amounts.

NAMED CITIES

Data on net incomes were computed for 32 named cities of more than 325,000 population. The highest mean net income for all physicians, $14,817, was reported for Memphis. Memphis also ranked first with $18,758 in the mean net incomes, by cities, of physicians in independent practice. In the first group Minneapolis ranked second, and Atlanta ranked second in the second group. The complete city rankings may be obtained from the article itself. We have serious doubts about the "representativeness"—in a generic sense— of the returns from these named cities despite the large number (30,000) of replies from the entire country and the statistical tests made by Weinfeld. More than he, we doubt that the information is sufficiently broad to warrant a statement that the mean or median net income in any category was higher in Memphis than in Atlanta or Minneapolis. Perhaps in our subsequent study of these returns we shall find reasons for more confidence in the averages for named cities.

BY SIZE OF CITY

Weinfeld classified cities into 11 sizes according to population; the smallest group was cities of less than 1,000 population and the top group, cities of 1,000,000 and over. City size variations in the cost of living are, of course, outside the scope of this study. It would seem a priori that the averages by size of city for the larger categories of physicians are probably more reliable than for some of the smaller categories and far more reliable than for named cities. A summary of Weinfeld's data on city size is presented in tables C and D. The highest mean net income for all physicians ($11,058 for the U. S.) was reported for cities of 250 to 500 thousand; the highest median income ($8,835 for the U. S.) was also reported for cities of 250 to 500 thousand—see row 12, columns 1 and 2 of Table C. For physicians whose major source of income was fees from independent practice (columns 3 and 4), the highest mean and median net incomes were reported for cities of 250 to 500 thousand; and the highest mean and median net incomes for physicians whose major source of income was salaried practice, cities of 25 to 50 thousand. For physicians whose entire source of income was from independent practice the highest mean and median net incomes were reported for cities of 250 to 500 thousand. For physicians in independent general practice (row 1a, Table D) the highest mean and median net incomes were reported for cities of 5 to 10 thousand (where the costs of living are usually relatively low); for partly-specialized (row 1b), cities of 10 to 25 thousand; and for fully-specialized, cities of 250 to 500 thousand. For physicians in salaried general practice the highest mean and median net incomes were reported for cities of 2.5 to 5 thousand; for partly-specialized, 1 to 2.5 thousand; for fully-specialized, 25 to 50 thousand; and for "Other" (mostly medical administrators), the highest mean net income was reported for cities of 1 million and over and the highest median net income for cities of 500 thousand to 1 million.

The small size of the samples casts some shadow of doubt upon some of these city size conclusions, especially those for physicians included under "Other." All physicians, particularly interns and residents contemplating a choice of location, will note this clear evidence from the city size data of the higher average net incomes (in dollars) for general practitioners in the smaller cities, for partly-specialized in the somewhat larger cities and for fully-specialized in cities of 250 to 500 thousand and that in no single instance (except for the physicians in the "Other" classification) is the highest mean or median net income reported for cities of 500 thousand and over or for towns of under 1 thousand. Other studies of physicians' incomes have noted the same feature of the returns from the very large cities. Although the representativeness of the samples is not perfect, it appears reasonably certain that the extremely large cities are over-supplied with physicians who might do better for themselves if they were located in other places where living costs may be lower. This conclusion is further supported by observations of numerous physicians who are in a position to give informed opinions. Weinfeld notes that the increases in 1949 over 1929 were greatest for cities under 5,000 and smallest for cities over 1,000,000. We sincerely hope that this survey of physicians' incomes will help in moving some of the physicians out of the extremely large cities. We fully appreciate the incompleteness of averages; some of the attractiveness of a metropolitan practice comes from the conviction of a physician making a choice of location that he will rise far above the average. On the other hand, rapid and extensive improvements in transportation have brought many of the small towns well within the economic and social orbits of the nearby cities, large and small. Income in 1949 per person engaged in agriculture (including forestry and fishing) had risen 253% since 1935-1939. Dollars of net income do not reveal the lower family living costs and the subjective appeals of a rural medical practice.

TABLE D.—*Size of City (Population in Thousands) with High and Low Average Net Income, by Degree of Specialization*

	High Mean Net Income		Low Mean Net Income		High Median Net Income		Low Median Net Income	
	Amount (1)	City Size (2)	Amount (3)	City Size (4)	Amount (5)	City Size (6)	Amount (7)	City Size (8)
1. Physicians in Independent Practice	$14,276	250-500	$7,109	Under 1	$11,970	250-500	$5,699	Under 1
1a. General Practice..............	10,586	5-10	6,596	Under 1	9,336	5-10	5,455	Under 1
1b. Partly Specialized.............	14,302	10-25	8,401	1,000 and over†	12,871	10-25	6,694	1,000 and over†
1c. Fully Specialized..............	16,608	250-500	11,885	1-2.5	14,210	250-500	8,000	1-2.5
2. Physicians in Salaried Practice....	9,157	25-50	7,019	Under 1	7,932	25-50	6,800	1-2.5
2a. General Practice..............	7,000	2.5-5	5,700	250-500	7,143*	2.5-5*	5,577*	1,000 and over*†

2d. Other	9,068	1,000 and over†	6,197	5-10	8,571*	500-1,000*	5,750*	5-10*
3. "All" Physicians...................	12,766	250-500	7,090	Under 1	10,195	250-500	6,177	Under 1

Source: Weinfeld, Tables 7, 9, 14 and 15.

* See footnote (*) to Table A.

† 1,000 and over means, of course, 1,000,000 and over.

WHICH SPECIALTY?

There will be considerable interest in the tables showing average net incomes for fully-specialized physicians by specialty. For the full specialists in independent practice, neurological surgery ranked first with a mean net income of $28,628 and a median net income of $24,500. Pathology ranked second with a mean of $22,284 and a median of $20,167. The median incomes are not influenced by the extremely large or the extremely small incomes reported by a few physicians. The rankings of specialty groups by medians is probably more reliable than by means; the two rankings, however, do agree for neurological surgery and pathology. The median ages of the respondents were 42 and 49 years, respectively. We are still in the process of developing age breakdowns which will enable us to make additional tests of the age representativeness of the returns from these specialists; this difference of seven years in the median ages of these two specialty groups seems, on the surface, excessive although pathology is one of the older specialties and neurological surgery is one of the newest. Weinfeld notes that the highest mean and median net incomes are reported for the specialties having very few members. Pathology also ranks second for the salaried full specialists with mean and median net incomes of $11,745 and $10,957, but roentgenology-radiology ranks first with $12,326 and $10,412. Again the author provides only the median age of those reporting, 41 years for pathology and 40 years for roentgenology-radiology. So much detail on the specialties is presented in the article that only this cursory summary of the highlights could be presented here.

FINAL COMMENTS

Our appreciation of the indebtedness of physicians and medical economists to the author, William Weinfeld, and to M. Joseph Meehan, Director of the Office of Business Economics, and the difficulties under which they have worked is so keen—among which has been our own inability to furnish them with certain data required for testing the representativeness of their many samples—that we would not at this time care to present many additional analytical comments. For many years to come their tabulations and interpretations of the returns from this survey will stand out as a basic reference point in future studies of physicians' incomes. Frankly, we were surprised that the maximum incomes were reported for ages 40-44 or 45-49 in most of the classifications for we had expected the peak earnings to be found later in life. Higher incomes of partners may be due to specialty, size of city, and age factors; partnerships and group practice are not synonymous terms even for partnerships of three or more members. But, as previously noted, we were unable to furnish the data necessary to eliminate the age factor as a variable. This is the outstanding defect of the study. The large sample (30,000) may actually make this prime defect of lesser importance than it now seems to us. Ideally, data for standardized age blocks should have been developed before the computation of over-all means and medians. Weinfeld also notes the over-response—a higher than expected percentage of replies—from specialists and, in the "Technical Notes," the over-response and under-response from certain states. He has made corrections for the latter, which produced negligible changes in the averages, but none for the former. There are also some indications of an over-response from salaried physicians.

The significance of this survey will probably change as time passes. At the present writing it seems to us that the important implications of this study are as follows:

1. The rise in physicians' incomes of the past dozen or 20 years has been at about the same rate as the rise in the national income per capita. More generally, the American people have been fair to their physicians in an inflationary era from the standpoint of income; and vice versa.

2. Talented high school graduates will continue to choose medicine for the age-old reasons—a great interest in the natural sciences and a conviction that a medical career will provide an opportunity to serve people. The inflationary 1940's have produced only one new financial reason for choosing medicine, namely, that medicine now pays better, on the average, than law—for the incomes of lawyers have not kept pace with the inflationary trends as have physicians' incomes. The trends

for certified public accountants and consulting engineers will doubtlessly be described in future surveys.

3. The highest 1949 average net incomes were not received by physicians in the larger cities where family living costs are high.

4. The differences between the average incomes of the all-salaried and the non-salaried physicians are considerable, but the value of the perquisites of the all-salaried physicians must be weighed.

5. The moderate increase in physicians' fees since 1935-1939, as reported by the United States Bureau of Labor Statistics, was only one of the three major factors responsible for the increase in the average incomes of physicians which has enabled physicians' incomes to keep pace with the inflationary trend of the 1940's. The other two major factors were the improved collections of fees and the increased "output per physician."

6. In addition to these three specific factors, the increase in the number of physicians since the base period must be considered. If there had been the nationwide shortage of physicians in 1949 which some writers have alleged, it is almost certain that physicians' incomes would have been, on the average, far higher and the increases in recent years far greater. This survey of physicians' incomes has revealed no general economic evidence of a national shortage of physicians.

BUREAU OF LEGAL MEDICINE AND LEGISLATION

MEDICOLEGAL ABSTRACTS

Malpractice: Failure to Use Roentgenograms to Locate Needle in Eye.—The plaintiff sued for damages allegedly caused by the negligence of the defendant physician. From an order dismissing the action, the plaintiff appealed to the Supreme Court of Washington.

In the performance of an operation upon one of the eyes of the plaintiff, the defendant physician inserted a number of minute metallic needles, each one of which had been threaded with black silk. When the operation was finished the needles were removed, but the defendant discovered that one of them was missing. There was one thread more than the number of removed needles. The defendant endeavored to locate the missing needle in the eye, but was unable to find it. No use was made of an x-ray to aid in discovering the needle. About eleven days after the operation, the defendant by use of x-ray equipment located the needle in the eye and removed it, but the plaintiff lost the use of that eye.

The Supreme Court said that when it was made to appear that the needle had been left in the plaintiff's eye, and that by the use of the x-ray its presence and location later became known, the jury would have had the right to infer that if the x-ray had been used before the operation was closed the presence of the needle would have been discovered and could have been removed. It may be, the court continued, that the condition of the eye was such that the presence of the needle would not have been discovered by the x-ray at the close of the operation, or there were other sufficient reasons why proper surgical practice justified omission of the use of x-ray at that particular time, but the burden was upon the defendant to go forward and submit evidence upon such questions. It was the duty of the defendant, when he either knew or had good reason to believe that the missing needle was or might be in the eye, to use available methods known to his profession to locate the missing needle. On the basis of this evidence, said the Supreme Court, the trial court should not have sustained the challenge to the sufficiency of the evidence. Accordingly the judgment in favor of the defendant physician was reversed and the cause was remanded for a new trial.—*Madis v. Stellwagen et ux, 227 P. (2d) 445 (Washington, 1951).*

MEDICAL MOTION PICTURES

Palmour Street; A Study in Family Life: 16 mm., black and white, sound, showing time 29 min. Produced in 1950 for Georgia State Department of Health by Southern Educational Film Production Service, Athens, Ga. Procurable on purchase ($50) from Health Publications Institute, Inc., Raleigh, N. C.

Basic concepts of mental health as they relate to family life are presented. The daily life of the Negro families living on Palmour St., Gainesville, Ga., serve to illustrate some of the ways in which parents influence the mental and emotional development of their children. Although the concepts are presented against the background of a Negro community, the same problems and situations apply in all homes. The demonstrations of both the mother's and father's love and the natural and real reactions of all the cast enhance the value of the film. It would stimulate a good discussion of family life.

This film is especially recommended for use with Negro church, parent-teacher, and other family groups. In selected instances it would also prove valuable for use with other adult groups. The photography, direction, and sound, are excellent.

Circulation: 16 mm., black and white or color, sound, showing time 16 min. Produced in 1950 by and procurable on purchase (black and white $75, color $150) from United World Films, 1445 Park Ave., New York.

This motion picture presents the elementary aspects of the anatomy and physiology of the circulatory system. The functions of the heart, veins, and capillaries and their general relation are shown by animated diagrams and by more detailed methods. A final sequence shows the making of a sphygmogram from the radial artery of a boy, before and after exercise.

The anatomy and physiology taught are correct in every respect, although the subject of the capillaries is handled superficially and the lack of labeling of right and left causes confusion when parts of the heart are described. The film would be most useful at the 7th, 8th, and 9th grade levels, since the omission of psychological emphasis and aims limits its use with adult groups. The photography and sound are very good.

House of Mercy: 16 mm., black and white, sound, showing time 17 min. Presented by RKO Pathe, This Is America Series. Produced in 1950 by Jay Bonafield. Procurable on 10 year lease ($80) from McGraw Hill Book Co., Text-Film Dept., 330 West 42nd St., New York 18, or on rental from Ideal Pictures Corp., 58 E. South Water St., Chicago 1.

This motion picture presents excellent general information about hospitals by the portrayal of a father who pays his first visit to the community hospital when he is notified that his son has been injured. After learning that his son is receiving expert attention, he makes a tour of various departments and discovers how scientifically and efficiently the members of the staff carry out their work. This man's enforced visit causes him to reflect on the importance of the hospital to the community.

The film is very informative, and the material presented is essentially accurate; however, it is lacking in motivation. It is recommended for all adult audiences and is especially useful for drives aimed at soliciting support for the establishment of community hospitals. The photography and sound are good.

Modest Miracle: 16 mm., black and white, sound, showing time 22 min. Produced in 1942 for Standard Brands, Inc., by Wilding Pictures Corp., Chicago. Procurable on loan from The Fleischmann Division, Standard Brands, Inc., 595 Madison Ave., New York.

Through a conference among a school principal, an undernourished grade school boy, and his father, the story of Dr. Robert R. Williams' isolation and synthesis of vitamin B_1 is portrayed. The enrichment of white bread with vitamin B_1 is also covered. The message of this film is fundamentally sound and interestingly told. However, the idea of having a school principal directly inform a pupil that he is undernourished is not to be considered as recommended practice. The implication that there was a large incidence of draftee rejection due to malnutrition in World War II may also be questioned.

If the above-mentioned portions of the film were corrected, it would be recommended for junior and senior high school students and adults. The photography and sound are excellent.

Generalized Torulosis with Bone Involvement. M. F. Wiener.—p. 713.

Treatment of Ulcerative Colitis and Regional Enteritis with ACTH.—Corticotrophin (ACTH) was given in doses of 20 to 40 mg. intramuscularly at six-hour intervals for periods of four to eight weeks to six patients with severe, extensive ulcerative colitis and two with regional enteritis. A significant and often dramatic remission in the acute aspects of the disease was induced in all but one of the patients. The remission was characterized by a notable decrease in diarrhea, disappearance or diminution of blood in the stools, improvement of the appearance of the mucosa on sigmoidoscopic examination (the mucosa did not revert to normal in any instance), relief of abdominal pain and tenesmus, prompt fall in temperature, sedimentation rate and fecal lysozyme titer, and an increase in appetite and weight, accompanied with a sense of well-being. No clinical response was observed in one patient with chronic ulcerative colitis of 23 years' duration, extensive fibrosis and cicatrization of the colon, multiple strictures, and perianal and perineal fistulas. Relapses occurred in three patients with ulcerative colitis and in both patients with regional enteritis within three weeks to nine months after corticotrophin treatment was discontinued. The relapses were mild in all but one patient, and there was a good response to a second course of therapy. Long-term maintenance therapy or repeated courses of treatment may be indicated in some patients. In two of the five patients who responded to corticotrophin therapy remission has lasted up to 16 months. The fecal lysozyme titer was found to parallel the course and activity of ulcerative colitis, decreasing with remissions and increasing with exacerbations. The level of fecal lysozyme is a measure of the activity of the disease process and is a significant index of the available functioning tissue and its ability to respond to injury. The remission induced by corticotrophin may prove exceedingly helpful in the preparation of patients with ulcerative colitis for surgical treatment. The best long-term results were obtained in patients receiving a prolonged course of treatment. Administration of the hormone does not constitute a cure but is a valuable adjunct in the therapy of ulcerative colitis and regional enteritis, particularly in the early stages of these diseases.

Tuberculin-Negative Tuberculosis.—Eleven patients with active tuberculosis and with negative cutaneous tuberculin reactions were observed. These patients were in good general condition and free from intercurrent nontuberculous infection. The presence of tuberculosis was established in six of the patients by the isolation of Mycobacterium tuberculosis from sputum culture. Acid-fast bacilli were seen on microscopic examination of the sputum in two patients, but tubercle bacilli were not isolated by culture. The bacteriologic examinations for tubercle bacilli were negative in the remaining three patients. Six of the patients were vaccinated with BCG; two became tuberculin reactors with a local papule after vaccination; one remained a tuberculin nonreactor but showed a possible "early reaction"; three showed no local reaction and remained nonreactors to tuberculin. Ustvedt's diagnostic tuberculin test resulted in no reaction in two other patients. In seven patients no reduction of normal skin sensitivity was demonstrated as judged by tests with codeine as a nonspecific irritant, the rate of absorption of a sodium chloride wheal, development of erythema after irradiation, and the incidence of passive dermographism. Some of the patients were examined for the presence of a tuberculin-neutralizing factor in the serum (so-called anticutin), which was found in one case

---

The Association library lends periodicals to members of the Association and to individual subscribers in Continental United States and Canada for a period of five days. Three journals may be borrowed at a time. Periodicals are available from 1940 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied with stamps to cover postage (6 cents if one and 18 cents if three periodicals are requested). Periodicals published by the American Medical Association are not available for lending but can be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted.

by tests in a guinea pig and in three human volunteers. Serum from another case appeared to contain "anticutins" when tested in three of the volunteers but not in another two persons. Sera from the remaining two patients were negative when tested in six human volunteers. The strain of M. tuberculosis (human type) isolated from one of the patients was studied in detail. A guinea pig became tuberculin-positive after inoculation with the strain. Vaccination of the patient's skin with the strain resulted in the development of cutaneous tuberculides without lymph node or general reactions as in tuberculin-positive tuberculous patients. Old tuberculin and purified protein derivatives prepared from the strain caused positive tuberculin reactions in controls of the same intensity as those developing by simultaneous testing with ordinary old tuberculin.

Cutaneous Inoculation Tuberculosis.—A comprehensive review of recorded treatments for cutaneous inoculation tuberculosis and eight recent case histories are presented. Persons who work with tuberculosis are always in danger of contracting the disease through skin inoculation. The review of the literature and two of the cases reported suggest that surgical excision of the tuberculous process usually results in a prompt cure. This treatment may shorten the course of the disease. If the cutaneous lesion and the involved lymph nodes are discrete and small, complete and immediate removal is the best method for cure. X-ray therapy has had general acceptance as a method of treatment per se and as an adjunct to other methods. It is, however, ineffective in caseous or abscessed glands. Streptomycin or other antituberculous drugs, either alone or in conjunction with surgery, are helpful in healing the disease. Incision and curettement of fluctuant nodes may be beneficial as a preliminary or final treatment of a particular disease area. Complete surgical excision of the skin lesions and of all other diseased tissue is the most rapid and satisfactory method for the treatment of patients with cutaneous inoculation tuberculosis.

Communicability of Histoplasmosis.—Prior and Cole made a pathological study of 12 dogs naturally infected with histoplasmosis to determine the various means by which Histoplasma capsulatum might be transmitted from dogs to other animals or human beings. Histoplasmosis developed in three of five dogs while they were exposed to eight dogs naturally infected with histoplasmosis. The three dogs gave negative reactions to the histoplasmin skin test before exposure to infected animals but showed histoplasmin reactivity within two to five months after exposure. No evidence of histoplasmosis was found in two dogs exposed to the animals with naturally occurring disease as well as to nine dogs with artificially induced histoplasmosis. Five dogs kept in a kennel with a dog found to have active histoplasmosis showed no evidence of the disease. In a group of 25 human household contacts of dogs with active histoplasmosis, there was no indication that any had the active disease. None of the eight laboratory workers showed evidence of active histoplasmosis after prolonged exposure to dogs with both naturally occurring and artificially induced histoplasmosis, although five had positive skin reactions. No evidence was found in this study suggesting the transmission of canine histoplasmosis to man, but its communicability from dog to dog was established. The dog should still be considered a potentially dangerous source of human histoplasmosis, because it has been demonstrated that the fungus can be disseminated via sputum, saliva or vomitus, feces, and urine.

Visceral Lesions and Endocrine Disturbances in Scleroderma.—Six women and two men between the ages of 18 and 48 with diffuse scleroderma were studied from the clinical and laboratory point of view. The following characteristic clinical changes were noted: involvement of the digestive tract with mucosal atrophy, absence of peristaltic movements and dilatation of the esophagus, stomach, and small bowel, with a rather characteristic small bowel syndrome; involvement of the cardiovascular system, with globular enlargement of the heart due to connective tissue lesions and subsequent dilatation; electrocardiographic changes showing incomplete or complete right bundle branch block, or extensive auricular and ventricular myocardial lesions; heart failure with atypical manifestations, such as bradycardia and absence of edema in the sclerodermatous skin; joint manifestations without characteristic radiographic changes and no evidence of chronic joint changes; bone decalcification of the parts in which mobility of the joints is diminished, and hypoadrenalism, as judged by increased blood potassium, positive reaction to the Kepler test, low 17-ketosteroids, lymphocytosis, and disturbance of the protein, cholesterol, and carbohydrate metabolism. A hyaluronidase skin test was performed in three patients, and a large spreading of the enzyme was observed. This could be due to a diminished adrenal hormone elaboration. Three of the eight patients were subjected to a therapeutic trial with irradiated ergosterol. Three hundred thousand units were given daily by mouth to each patient, and, in addition, 500,000 units were given intramuscularly twice a week. While no modification of the general condition or of the visceral lesions was observed, the scleroderma of the skin was much improved. The changes observed were softening of the skin, better joint movements, and, from the histopathological point of view, a decrease of the connective tissue proliferation.

Lymphangitic Carcinomatosis of the Lungs.—The occurrence of lymphangitic carcinomatosis of the lungs is reported in six men between the ages of 46 and 71. Symptoms referable to the primary neoplasm were frequently absent, even up to the time of death. In some patients the symptoms due to the primary neoplasm were present but masked by the pulmonary symptoms. The most striking and constant observation was severe dyspnea, which appeared to be progressive and constant. Cough occurred in five patients and was productive of only small amounts of white, tenacious, occasionally blood-tinged sputum in three patients. Other striking features were general physical deterioration and cyanosis. Examination of the lungs disclosed relatively few signs, usually medium rales or occasionally sibilant rales with no evidence of consolidation. Evidence of cor pulmonale was revealed by electrocardiograms in three of the patients. The occurrence of a spontaneous pneumothorax in one patient was probably a result of a rupture of a subpleural bleb associated with compensatory emphysema. The roentgenograms of the chest revealed a pattern of thin, stringy lines with frequent interweaving branching out from the hilum. If such a roentgenogram is found with the above-mentioned symptoms, and miliary tuberculosis, fungous diseases, and occupational diseases are ruled out, lymphangitic carcinomatosis of the lung should be suspected. Sputum showed tumor cells in the two patients with bronchogenic carcinoma and pulmonary alveolar carcinoma respectively, although it is usually negative in carcinoma metastatic to the lungs. The method of spread of the neoplasm to the lymphatics of the lungs is probably by retrograde lymphatic permeation, with the tumor cells growing along lymphatic channels. In three patients the spread was from primary carcinoma of the stomach. Spreading of the tumor along the paraesophageal lymphatics thence through the hilar anastomoses into lung parenchyma as well as through a hematogenous route had been suggested. Necropsy was performed in all six cases and consistently showed fibrosing perivascular, vascular, and pulmonary changes regardless of the primary site of the carcinoma. These were of a degree sufficient to explain at least in part the clinical findings.

Alveolar-Cell Carcinoma of the Lung.—A man 60 and a woman 31 with alveolar-cell carcinoma are reported on. Dyspnea and cough were observed in both patients, who died in respiratory distress. Conclusive evidence of a malignant neoplasm was revealed by cytological examination of the bronchial aspirates in the female patient. A four-day course of nitrogen mustard therapy (methyl-bis [beta-chloroethyl] amine hydrochloride, 1 mg. per kilogram of body weight) was instituted, but it in no way altered the course of the disease. Necropsy in both cases revealed the characteristic microscopic findings of alveolar-cell tumors: In all lobes the lining of the alveoli varied from single-layered to pseudostratified and was made up of nonciliated cells varying from high cuboidal to columnar. The nuclei appeared hyperchromatic, large, and vesicular. The cells were pleomorphic, and some contained several nuclei. Mitotic figures could be demonstrated. There were papillary projections into the alveoli and exfoliation of single or groups of tumor cells. The cytoplasm and nuclei of the desquamated cells assumed a round to oval form. Except for some thickening, the alveolar walls were for the most part unaltered. At the periphery of the lung, uninvolved alveoli were present. No involvement of the bronchial tree was noted. The tumor cells did not resemble ciliated cells of bronchial epithelium. The site of origin is unexplained. The male patient had worked for 37 yr. with a mixture of tar, linseed oil, glycerin, and glue, while the female patient had worked for two years with an unproved irritant, consisting of zinc oxide and rosin dust. Although not yet conclusive, the bulk of evidence suggests that an alveolar lining may proliferate and give rise to tumors in response to various specific agents. In both of the author's cases the alveolar lesions could not be differentiated microscopically from so-called pulmonary adenomatosis. This resemblance has led to the suspicion that pulmonary adenomatosis is potentially malignant or precancerous. The striking morphological resemblance of pulmonary adenomatosis in man to jaagsiekte in sheep has been stressed. Pulmonary needle aspiration biopsy and cytological examination of sputum and bronchial washings are suggested as diagnostic measures.

Potassium Iodide and Streptomycin.—Fifty-eight patients with far-advanced pulmonary tuberculosis with long-standing cavitation were selected for treatment. None had received streptomycin previously, and all had positive sputum at the beginning of treatment. Twenty-three patients received streptomycin alone for a period of 120 days, and 35 received combined treatment with streptomycin and potassium iodide over a similar period. Streptomycin was administered intramuscularly in a single injection of 1 gm. daily to each patient of both groups. Patients in the combined therapy group received, in addition, a total of 4 gm. of potassium iodide daily orally, administered in solution in three equal doses morning, noon, and night. All patients were restricted to complete bed rest and received a high protein, high carbohydrate diet. No evidence was found of any significant differences in temperature, pulse, respiration, erythrocyte count, or total or differential leukocyte count between the controls and the group receiving combined therapy. Four of the 23 patients in the control group and seven of the 35 in the combined therapy group ended the treatment period with three consecutive negative sputum examinations. Streptomycin-resistant organisms emerged in about half the cases between the 60th and 90th day, and by the end of the treatment period in all but six patients organisms had developed that were resistant to streptomycin in concentrations of 10 γ per cubic centimeter. Three of these six patients were in the control group; the other three were in the combined therapy group. Significant roentgenographic and nutritional changes were noted infrequently in the control group. Much improvement was noted in both chest roentgenogram changes and in weight in the combined therapy group. No evidence was found that potassium iodide was harmful in tuberculosis when administered in conjunction with streptomycin. The small cavities in the lungs of five patients receiving streptomycin and potassium iodide closed completely. For this reason it is believed that in selected cases this treatment may avert the need for surgical collapse therapy. Moreover, certain far advanced inoperable patients may be salvaged and made more suitable for surgical intervention.

Streptomycin and Artificial Pneumoperitoneum.—Treatment with streptomycin and pneumoperitoneum combined and with pneumoperitoneum alone was given to 117 patients with far-advanced pulmonary tuberculosis. In 11 patients, seven treated with the combined therapy and four with pneumoperitoneum alone, therapy was discontinued after an average of 2.2 mo. because it was ineffective or because the patient was lost to observation. Of the remaining 106 patients, 20 were treated in preparation for surgery and 86 had conservative treatment only. In the first group, 13 received the combined treatment and seven received pneumoperitoneum alone; in the second group, about half received the combined treatment and half received pneumoperitoneum alone. Before therapy, the patients being prepared for surgery had bilateral disease and an exudative component that precluded pneumothorax or any form of major surgery. After therapy, none of them had negative sputum and all but one had open cavities; however, all had some roentgenological clearing. Of the patients not being prepared for surgery, 77% had closed cavities after pneumoperitoneum alone and 80% had sputum conversion. In the combined therapy group, only 62% had closed cavities and 61% had negative sputum after treatment; however, in this group the disease was originally more exudative. It is concluded that the length of treatment with pneumoperitoneum is important in determining the eventual outcome of the case but the extent and character of the disease at the beginning of treatment are the deciding factors. The role of streptomycin and pneumoperitoneum in the restoration of the damaged drainage mechanism of the lung are discussed.

Psychotherapy of Ulcerative Colitis.—Because the emotional state of the patient is important in the course of ulcerative colitis the authors treated 12 male and 17 female patients with this disease by a supportive form of psychotherapy. Eighteen of the 29 cases were rated severe and 11 moderately severe. After a control period of at least 10 days, during which the patients were treated with bed rest and, if necessary, with rehydration and blood transfusions, psychotherapy was started. Psychoanalysis was not used in these cases. The authors explained to the patients that they were engaged in a study of relationships between life situations and disease in general. Most patients were eager to cooperate in this study. The patient was given an opportunity to discharge his aggressive feelings and he was given constant sympathy and protection, so that he might reassert himself. Improvement of social conditions and change in the attitude of parents, marriage partners, or employers also had a favorable effect on the course of the disease. The realization on the part of the medical and nursing staff that patients with ulcerative colitis are immature persons who should be treated as such and that the disease itself has contributed to their regression into more infantile feelings and behavior patterns has been important in obtaining satisfactory results. Fourteen of the 29 patients were clinically cured at the time of discharge. Temperature and sedimentation rate were normal, the bowel movements reduced to one or two a day, and the stools free of pus or mucus and of solid or semisolid consistency. X-ray findings did not return to normal, but the patients remained clinically cured for periods varying from one to nine years. Eight patients returned for one or more recurrences after initial cure. All these recurrences yielded to treatment along the same lines. In general, the success of treatment depended on the duration of the illness before psychotherapy was instituted, on the physical condition of the patient on admission, the time and care the physician was prepared to give him, and the cooperation obtained from those in the patient's environment. This type of "superficial" psychotherapy could be carried out as well by an internist as by a psychiatrist, provided that he is sufficiently interested. The results compared favorably with those obtained by certain forms of medical or surgical treatment.

Effects of Cream on Blood Coagulation.—Thirty patients who were routinely admitted to the hospital fasted for 12 hr. before a first sample of blood was collected by venipuncture for measuring the venous clotting time; then they were fed 60 ml. of 20% cream from cow's milk. The clotting time of whole venous blood was then measured at one-half hour, one, two, and three hours after ingestion of the cream. Control experiments, in which 60 ml. of water was used in place of the cream, were performed for determination of the normal fluctuations of the rate of coagulation over a four hour period with repeated venipunctures. Within one-half hour after the oral ingestion of cream the clotting time of whole venous blood was definitely decreased; the decrease occurred within one-half hour and reached a maximum in one hour persisting with minor fluctuations for the three hour observation period. A total of 100 patients were studied for varying periods with similar results. Subsequently, dilution of normal fasting blood with 10% cream in 0.85% isotonic sodium chloride solution produced a great drop in coagulation time. This suggests that cream may have a local hemostatic effect. In addition it may be expected to inhibit gastric motility, depress secretion, and act as a buffer on gastric acid. The early feeding of milk and cream in gastrointestinal bleeding would appear to be justified on a physiological basis.

Periarteritis Nodosa: *Late Results with ACTH.*—Metabolic studies of the effect of pituitary adrenocorticotropic hormone (ACTH) in a patient with periarteritis nodosa were continued for 145 days. Clinical and pathological remission occurred. Cure was not effected, but pronounced physical improvement has been sustained for 14 months. The eosinophils decreased dramatically with pituitary adrenocorticotropic hormone and disappeared from the peripheral blood after 48 hours. They did not reappear until two days after discontinuance of therapy. Changes in the eosinophil count were correlated closely with metabolic effects and clinical progress. The hormone had a pronounced catabolic effect on nitrogen balance; administration of 40 mg. daily produced a strongly negative nitrogen balance while the patient was on a maintenance diet; this dosage was also sufficient to negate completely the marked nitrogen retention induced by a high protein, high caloric diet. Evidence is presented that this effect was due to the hormone and not merely to repletion of body protein. There was temporary moderate retention of sodium and chloride during the first days of each course of pituitary adrenocorticotropic hormone therapy, followed by an escape from adrenal cortical control, as evidenced by reestablishment of equilibrium. The effect of pituitary adrenocorticotropic hormone on potassium was in most respects opposite to that on sodium and chloride. An early potassium diuresis occurred while salt was being retained, followed by potassium retention and then a gradual increase in urinary excretion until the balance became distinctly negative. Pituitary adrenocorticotropic hormone caused a definite increase in fecal and urinary loss of calcium and phosphorus. Once full effect was obtained by 40 mg. of the hormone per day, successive decrements in dosage were not accompanied by proportionate decreases in the excretion. The metabolic responses to the hormone were similar to those observed in normal persons. The authors conclude that maintenance of adequately high levels of adrenal cortical function with relatively smaller amounts of pituitary adrenocorticotropic hormone seems feasible after the gland has been stimulated with sufficiently large priming doses.

Acute Subdural Hematoma.—Any patient seen in the emergency ward after head trauma who shows progression in neurological changes and deepening of the state of unconsciousness requires exploratory trephination immediately, so that the actual bleeding points may be found and sealed off. It has been the author's experience in cases of massive acute subdural hematoma that the bleeding has originated at the base rather than the vertex. In the presence of clots large enough to cause signs and symptoms by compression, the bleeding is usually from the inferior cerebral veins running from the inferior surface of the temporal and occipital lobes to the transverse sinus, sphenoparietal sinus, and superior petrosal sinus. These veins may be lacerated or even torn from the sinus, with severe, rapid bleeding. The author's operative approach permits rapid accessibility to the commonly involved vessels. Two cases of acute subdural hematoma following automobile accidents are reported in which this more posterior approach was used. A curved incision is carried posteriorly above and behind the ear and, depending on the patient's condition and the rapidity of blood loss, a small bone flap is turned down, hinged on the temporal muscle, when speed is less important, while the muscle is stripped downward from the bone and the bony defect rapidly enlarged with the rongeurs in cases in which speed is essential. Bleeding from veins or sinuses is stopped by cautery, absorbable gelatin sponge, (gelfoam®), and thrombin solution. The dura is left open to permit postoperative decompression. The muscle is closed over the bony defect. No cranioplasty was considered necessary at a later date in these cases. A certain number of patients with acute subdural hemorrhage have little or no brain damage other than secondary to compression by clot. With immediate action and in some cases with the outlined modified operative approach many of these patients can be saved.

Bronchial Adenoma.—Four cases of bronchial adenoma are discussed. Attention is called to the confusion resulting from the use of varying and nondescript nomenclature. It is suggested that "adenoma" be reserved for the group as a whole and that "carcinoid adenoma" and "mixed tumor adenoma" be exclusively subclassifications. The term "cylindroma" should be discarded. Until 1937 little question was raised regarding the supposedly benign nature of these lesions, and major surgical procedures were undertaken only when necessitated by complications. Since then various improvements in surgical techniques and methods of treatment and the continual reports indicating malignant characteristics in these lesions have demonstrated that surgical exploration, usually with resection, should be the preferred method of treatment. If the tumor invades at all, then only rarely will it be possible to remove it bronchoscopically with certainty that it has been adequately removed. Only surgical exploration can offer clear evaluation of the condition and permit definitive treatment, because the bronchial adenoma extends or metastasizes peribronchially and to the mediastinum. The authors conclude that in the majority of cases surgical exploration with lobectomy or pneumonectomy and removal of mediastinal nodes, where indicated and possible, is the procedure of choice. In any patient suffering from repeated episodes of pulmonary inflammation, chronic cough, and hemoptysis, without adequate explanation, bronchial adenoma should be suspected and ruled out.

Cat-Scratch Fever.—The occurrence of cat-scratch fever is reported in a man 36, who two weeks before admission to the hospital awakened to find his cat licking the left side of his neck in an area containing two pimples. He was scratched on the right hand at about the same time. Ten days before admission the patient noted a painless swelling of a lymph node on the left side of his neck, which increased to the size of a hen's egg. The temperature rose to 102 F., and a pinkish macular rash that gradually developed into small vesicles was noted over the extensor surfaces of the patient's arms. Nose and throat cultures were negative for pathogenic agents as were tularemia agglutination tests. The patient's cervical lymph node spontaneously drained on the fourth hospital day. It was cultured, a skin antigen prepared from the material by the classic Frei procedure, and 0.1 cc. was injected intradermally. A positive reaction was noted at 24 and 48 hr. Six control patients showed no reaction to intradermal injection of this material. An intradermal injection of 0.1 cc. of an antigen prepared by Foshay from a former cat fever patient's bubo was given to the patient, and a positive reaction was observed at 24 hr. The reaction was maximal at 48 hr. and persisted for a few days. The antigen was tested on six control patients; no reaction was noted. These results seem to indicate a high specificity of this antigen. The term cat-scratch fever was coined by Foshay of Cincinnati for the disease characterized by a history of domestic cat scratches followed by a systemic infection with malaise and fever in which the brunt of the infection is borne by the lymph nodes. Occasionally, lesions similar to exanthems or erythema nodosum may occur. The infective agent has never been isolated but is apparently a virus; it is present in the pus from lymph nodes involved and produces a specific skin reaction when made into an antigen. No specific therapy is yet indicated.
